**Abstract:** Precise flow measurement is pivotal in hydraulic systems, serving as an essential parameter for fluid power control. When combined with pressure data, it also facilitates calculating hydraulic power, proving invaluable for applications like predictive maintenance. Conventional flow sensors in fluid power systems are typically invasive, often disrupting the flow and delivering unreliable measurements, particularly during transient conditions. One common approach relies on determining the flow rate by measuring the pressure difference along a pipe and applying the Hagen-Poiseuille law, constrained to steady, laminar, and incompressible flows. This study presents the capability of a previously introduced analytical soft sensor to determine transient pipe flow for non-laminar flow rates. This method does not require a flow rate sensor and utilizes two pressure transducers to determine the pipe flow. Furthermore, the relevance of filtering is investigated, and the robustness of the soft sensor is demonstrated by the outcome that even basic filtering results in a good match between the soft sensor and test rig. The findings underscore the soft sensor's capability to deliver accurate and computationally efficient measurements of transient volumetric flow based solely on pressure data for laminar and non-laminar flow with simple filtering of real-world signals.

**Keywords:** soft sensor; volumetric flow rate determination; non-laminar flow; signal filtering

## 1. Introduction

Measuring volumetric flow guarantees hydraulic systems' optimal performance and longevity. Accurate flow rate data is essential for condition monitoring, predictive maintenance, and control engineering in both mobile and stationary hydraulic systems. When combined with pressure measurements, flow rate enables the calculation of hydraulic power, which is a critical parameter for assessing system efficiency and identifying potential losses. Furthermore, volumetric flow represents a crucial control variable in fluid power systems.

The current range of volumetric flow sensors has two significant limitations. Many of these sensors are invasive, requiring installation within the pipe and often utilizing turbines or rotors that disrupt the flow and add mechanical complexity. Furthermore, these sensors frequently depend on inert components, which diminishes their efficacy at high frequencies. For instance, gauging pump pulsations is difficult, as the pulsation frequency depends on the pump's displacement units and rotational speed, often exceeding the range of conventional sensors. These limitations underscore the need for alternative solutions. The ideal sensor would be minimally invasive, capable of detecting transient flow conditions, and function as a soft sensor by leveraging the pressure signals already present in hydraulic systems.

The concept of deriving flow rates from pressure signals has a long history. Analytical methods for calculating volumetric flow date back to the 19th century, with the Hagen-Poiseuille (HP) law being one of the most well-known. While this law is effective for steady, laminar flows, it does not account for transient or high-frequency effects. The Richardson effect is an example of a phenomenon affecting

higher frequencies' velocity profiles [1]. By incorporating a dynamic term into the HP equation, it is possible to estimate transient flow rates. This study builds on these principles by introducing a soft sensor to compute transient flow rates based on pressure data.

In previously published work, an analytical soft sensor has been derived, which computes transient, compressible pipe flow based on pressure transducer signals [2,3]. This soft sensor has been validated by parameter-distributed simulations and with real-world data provided by a for this soft sensor specifically constructed test rig [4,5]. The validation has been conducted for pipe flows inside the laminar regime and should now be extended to non-laminar flow. Furthermore, the importance of filtering the real-world pressure signals is one of the main scopes of this research.

This paper is structured as follows: Section 2.1 provides an overview of volumetric flow measurement techniques and models. Afterward, the basic structure for the analytical model is introduced in Section 2.2. Section 2.3 presents the test rig for the validation, and eventually, the investigated test cases are described in Section 2.4. In the following Section 3, the results are presented, and eventually, discussion and conclusion are provided in Section 4.

## 2. Materials and Methods

### 2.1. Flow Rate Measurement Methods & Models

Accurate measurement of volumetric flow is a fundamental aspect of optimizing fluid systems' performance and is a key driver in developing a range of sensor technologies. These sensors are broadly classified into two categories: invasive and non-invasive.

Invasive sensors, such as positive displacement and turbine flow meters, measure flow by tracking the movement of fluid volumes over time. However, the inertia of their components limits their ability to measure transient flows [6] accurately. A common invasive approach is to measure the pressure drop across a flow-restricting component, such as an orifice [7], using the following equation:

$$Q_O = \alpha_D A_D \sqrt{\frac{2\Delta p}{\rho}} \quad (1)$$

This relationship depends on parameters such as orifice geometry  $A_D$ , discharge coefficient  $\alpha_D$ , fluid density  $\rho$ , and pressure difference  $\Delta p$ . While viscosity has minimal effect, obstructions disrupt flow patterns. Differential pressure meters, which rely on Bernoulli's principle, struggle with unsteady flows and become unreliable for frequencies above 2 Hz [8]. Other invasive methods, such as vortex flow meters and hot-wire anemometry, face challenges in low turbulence or provide localized measurements, often disturbing the flow.

Non-invasive sensors, including electromagnetic and ultrasonic flowmeters, do not disturb the flow. Electromagnetic flowmeters require conductive fluids, making them unsuitable for most hydraulic oils [7]. Ultrasonic flowmeters, while capable of transient flow measurement, assume symmetrical flow profiles, reducing accuracy in turbulent conditions [9].

Advanced minimally invasive techniques, such as particle image velocimetry and Coriolis flowmeters, offer innovative solutions but face practical limitations. Particle image velocimetry requires transparent tubes and seeding particles, while Coriolis flowmeters are constrained by tube resonance frequencies that limit response times [7,10].

Despite advances, most sensors are ill-suited for transient flows. They either lack the necessary response times or impose impractical requirements for industrial applications.

The recent advancements in transient flow measurement have resulted in the development of innovative methods and models that have enhanced the accuracy and reliability of the field. Brereton et al. introduced techniques for laminar pipe flow, relating flow rate to the history of pressure gradients without assuming velocity profiles [11]. Subsequently, an alternative approach was proposed, linking flow rate to centerline velocity history [12]. Sundstrom et al. enhanced friction modeling, thereby markedly reducing errors in the pressure-time method for hydraulic flow measurement [13]. Foucault et al. developed a real-time laminar flow estimation method based on differential pressure

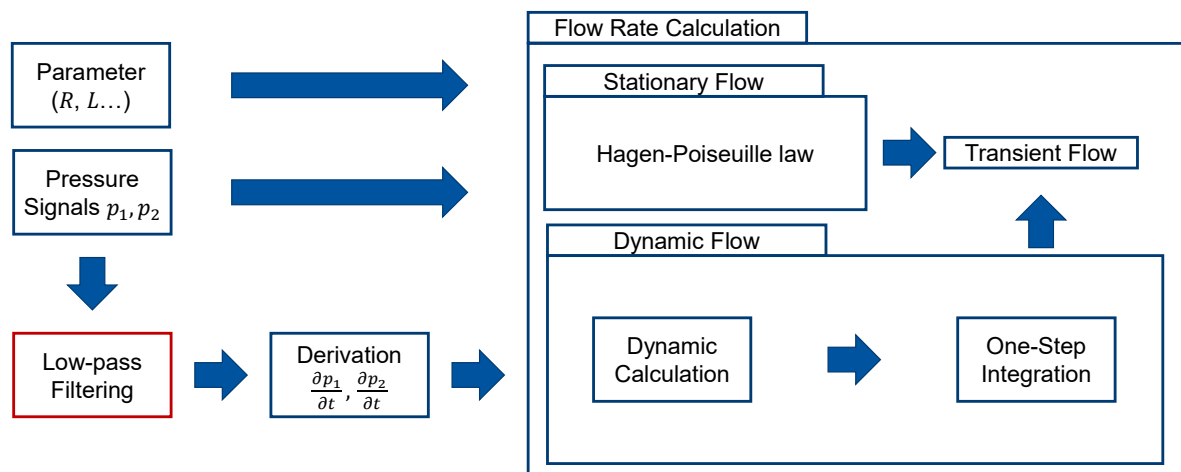

measurements and kinetic energy principles [14]. García et al. furthered the study of turbulent flow, developing models to simulate unsteady flow responses and laminarization phenomena [15,16].

In their comprehensive reviews of analytical models for accelerated incompressible fluid flow, Urbanowicz et al. addressed the challenges inherent in turbulent flow predictions [17]. Additionally, they developed analytical solutions for laminar water hammer phenomena and wall shear stress during water hammer events, which were validated by simulations and experiments [18].

Bayle et al. advanced the field of wave propagation models in viscoelastic pipes, creating a rheology-based model and a Laplace-domain approach applicable to diverse boundary conditions [19, 20]. These developments span methods for transient flow estimation, improved friction and wave propagation modeling, and analytical solutions, enabling more accurate measurements for laminar and turbulent flows.

## 2.2. Pressure-Based Flow Rate Soft Sensor

An overview of the calculation steps within the soft sensor is given Figure 1. The steps include setting the system parameters, such as the pipe's radius and length, and measuring the two input pressure signals. For the calculation, the soft sensor needs the derivative of the pressure signals. To take the derivative, the pressure signals must be filtered to handle the noise in the measurements. Afterward, the stationary and the dynamic flow rate can be calculated. Combining these two yields the final transient flow rate.

**Figure 1.** Flowchart for the flow rate calculation using the soft sensor.

The stationary flow rate is calculated using the HP law. HP describes a law for the stationary incompressible laminar volumetric flow rate for flow in a straight pipe. The law connects the flow rate  $Q$  to the pressure drop over the length of the pipe  $\Delta p$  through the hydraulic Resistance  $R_H$  as seen in Equation 2.

$$Q = \frac{\pi R^4}{8\eta L} \Delta p = \frac{1}{R_H} \Delta p \quad (2)$$

Here, the pipe radius is  $R$ , the dynamic fluid viscosity is  $\eta$ , and the pipe length is  $L$ . A flow is considered laminar if the dimensionless Reynolds number (Re) is less than 2300. Hereby, the Re number is defined as  $Re = \frac{\rho v D}{\eta}$ , with  $\rho$  as the density of the fluid,  $v$  as the axial fluid velocity,  $D$  as the pipe's diameter, and  $\eta$  as the dynamic viscosity.

In a first work, Brumand-Poor et al. [2] expanded the law of Hagen and Poiseuille to include transient incompressible flow rates. In a further work by Brumand-Poor et al., [3], compressible phenomena were incorporated in the equation for the volumetric flow rate. The resulting equation consists of a stationary part (compare Equation 2) and a dynamic part, which includes the transient and compressible behavior of the fluid and is presented in Equation 3:

$$Q_2(t_n) = \frac{1}{R_H} \Delta p - \frac{1}{R_H} \left[ \int_0^{t_n} W_{1,dyn}(t_n - \tau) \frac{\partial p_1(\tau)}{\partial t_n} d\tau - \int_0^{t_n} W_{2,dyn}(t_n - \tau) \frac{\partial p_2(\tau)}{\partial t_n} d\tau \right]. \quad (3)$$

The dynamic part consists of a convolution integral between the dynamic weighting function and the time gradient of the pressure at the pipe's inlet ( $p_1$ ) and outlet ( $p_2$ ), respectively. The weighting functions can be split into two parts, one part describing the transient nature of the fluid ( $W_{inc}$ ), which is the same for both the inlet and outlet, and one describing the compressible effects at the relative ends of the pipe ( $W_{comp}$ ).

$$W_1(t_n) = W_{inc}(t_n) + W_{1,comp}(t_n) \quad (4)$$

$$W_2(t_n) = W_{inc}(t_n) + W_{2,comp}(t_n) \quad (5)$$

A comprehensive derivation and validation with a parameter-distributed simulation of the incompressible and compressible weighting functions are provided in [2] and [3], respectively, and are out of the scope of this paper.

The dynamic weighting functions are then obtained by subtracting the stationary value:

$$W_{1,dyn}(t_n) = W_1(t_n) - 1 \quad (6)$$

$$W_{2,dyn}(t_n) = W_2(t_n) - 1 \quad (7)$$

The convolution integrals in the solution in Equation 3 can be simplified to a one-step integration method as shown in Brumand-Poor et al. [3], thus simplifying the evaluation of the volumetric flow rate.

$$Q_2(t_n) = Q_{2,stat}(t_n) - [Q_{2,dyn,1}(t_n) - Q_{2,dyn,2}(t_n)]. \quad (8)$$

$$Q_{2,dyn,1}(t_n + \Delta t_n) \approx \frac{1}{R_H} \sum_{i=1}^N \left[ Y_{0,i}(t_n) e^{-n_i \Delta t_n} + \Delta \dot{p} \frac{m_i}{n_i} (1 - e^{-n_i \Delta t_n}) \right]. \quad (9)$$

$$Q_{2,dyn,2}(t_n + \Delta t_n) \approx \frac{1}{R_H} \sum_{i=1}^N \left[ Y_{0,i}(t_n) e^{-n_i \Delta t_n} + \Delta \dot{p} \frac{m_i}{n_i} (1 - e^{-n_i \Delta t_n}) \right]. \quad (10)$$

Here,  $Y_0(t_n)$  is the solution for the dynamic flow rate from the previous timestep.  $m_i$  and  $n_i$  are the coefficients of the weighting functions in the time domain.  $\Delta \dot{p}$  is the pressure difference gradient averaged over the timestep  $\Delta t_n$ .

Further research was conducted regarding the equation for the volumetric flow rate as a soft sensor for real-world applications. In the work of Brumand-Poor et al. [5], the equation was compared to data from a test rig for laminar flows.

The investigations of the soft sensor applied to a real-world test rig showed that filtering is necessary due to signal noise, which does not occur in simulations. That is caused by the fact that the sensor takes the derivative of the pressure signals. By taking the unfiltered derivative, the noise carried by the signal will get amplified, which makes it unusable for calculations. Filtering alters the amplitude and the phase of an investigated signal. Therefore, this work examines whether a basic filter with a small modification of the actual signal is suitable for the soft sensor. Therefore, this work proposes a simple first-order 'Butterworth' filter [21] to pre-process the pressure signals before taking the derivative. This type of filter has a smooth passband without ripples and reduces the signal amplitude with frequencies above a cut-off frequency that the user can set. Therefore, this filter can effectively dampen high-frequency noise. Unlike the Chebyshev filter, which introduces ripples, or the

Bessel filter, which has a slow roll-off, the Butterworth filter attenuates noise while preserving signal integrity, ensuring accurate results. Furthermore, only first-order filtering was applied to minimize the effect of altering the amplitude and phase of the signal.

The current work investigates the effect of two different cut-off frequencies on the soft sensor's accuracy. The test cases presented in this work show that a filter with a generic cut-off frequency of 100 Hz, independent from the frequency that should be measured, greatly improves the soft sensor's results. Furthermore, an adequate cut-off frequency is applied to further investigate the filtering effect on accuracy. A filter with 100 Hz has a cut-off frequency so far away from the actual frequency of the investigated pulsations that the phase shift can be neglected for the investigated frequency range.

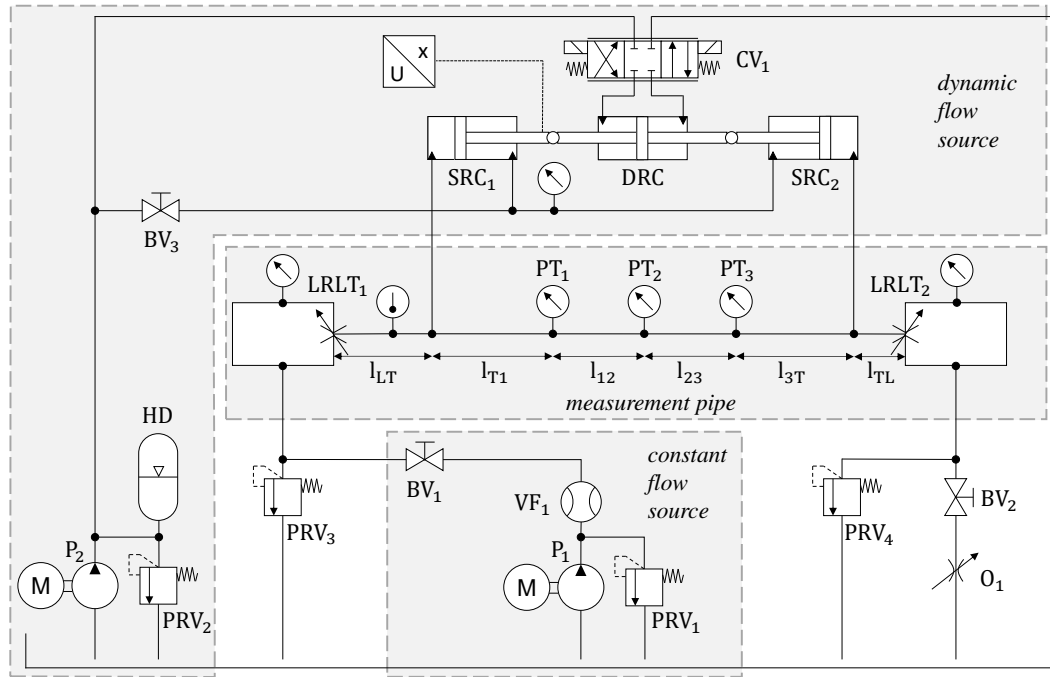

### 2.3. Test Rig

The test rig was developed in a prior publication [4] and constructed and utilized to validate the soft sensor in another work [5]. A detailed description of the development and setup is provided in [5].

A dedicated test rig was developed to validate the derived system equations for the soft sensor. Its primary function is to generate a known transient flow rate through a hydraulically smooth, straight pipe that satisfies the assumptions underlying the system equations. The device must also provide pressure measurements at a minimum of two positions along the pipe. These pressure signals are used to calculate the pressure difference required by the system equations. The volumetric flow rate obtained from these calculations is then compared to the flow rate generated by the test rig.

The test rig must provide a range of flow conditions, including laminar and turbulent Reynolds number regimes and stationary and pulsating flows. The most effective method of generating pulsations is to use the motion and geometric displacement of a hydraulic cylinder [4]. The displaced volumetric flow can be approximated by using the kinematics of the cylinder, expressed as  $Q_c = A\dot{v}$ . When using this method, it is critical to consider the limitations imposed by compressibility and pressure wave propagation, as neglecting these factors can lead to significant errors in the computation of the flow rate determined by the cylinder movement. To mitigate errors caused by compressibility effects, it is beneficial to operate at higher pressures as this increases the bulk modulus  $K$  and makes it more stable.

Additional errors are introduced by wave reflections within the pipe, which occur when changes in characteristic impedance reflect pressure waves. These impedance changes can result from installations along the pipe or variations in cross-sectional geometry [22]. Therefore, minimizing cross-sectional transitions and terminating the measurement pipe with a low-reflection line terminator (LRLT) is important. An LRLT typically consists of an orifice, a variable cross-section adjustment mechanism, and a downstream volume. By matching the orifice's cross-section to the pipe's characteristic impedance, the LRLT mimics an infinitely long pipe, preventing wave reflections and allowing pressure waves to dissipate in the termination volume. An illustration of the hydraulic circuit of the test rig is provided in Figure 2.

**Figure 2.** The hydraulic circuit of the test rig. [5]

The main feature of the test rig is a measuring pipe with a length of 3.22 m with three designated points for pressure monitoring. The distances between the pressure transducers  $PT_1$  and  $PT_2$ , and  $PT_2$  and  $PT_3$  are  $l_{12} = 0.33$  m and  $l_{23} = 0.47$  m, respectively. To mitigate pressure wave reflections, the measuring pipe is equipped with  $LRLT_{1,2}$  at both ends. Each LRLT is located  $l_{LT} = l_{TL} = 0.36$  m from the nearest T-junction. In addition, an adjustable orifice,  $O_1$ , is used to regulate the pressure within the pipe to minimize compressibility effects.

The steady flow system connected to  $LRLT_1$  includes a hydraulic pump ( $P_1$ ), a pressure relief valve ( $PRV_1$ ), and a volumetric flow sensor ( $VF_1$ ). On the other side, the dynamic flow source integrates a double-rod cylinder (DRC) that drives two single-rod cylinders ( $SRC_{1,2}$ ), generating fluctuating volumetric flows. The T-joints connecting the measurement pipe to the dynamic flow source are positioned  $l_{T1} = 1.5$  m from  $PT_1$  and  $l_{3T} = 0.2$  m from  $PT_3$ , providing sufficient inlet and outlet zones.

The double-rod cylinder is controlled by a servo valve  $CV_1$ , which adjusts the amplitude and waveform of the flow, allowing a range of operating scenarios. Piston velocity is tracked by a position sensor mounted on one of the rods. The dynamic flow system also includes a second hydraulic pump ( $P_2$ ), a pressure relief valve ( $PRV_4$ ), and a set of switching valves ( $SV_3$ ). The switching valves are configured to pre-pressurize the single-rod cylinders, thereby balancing the forces exerted by the pressure within the sensing pipe and reducing the mechanical stress on the connections. The coupling mechanism between the single-rod cylinders ensures a constant volume of fluid in the pipe as the suction of one cylinder compensates for the displacement of the other.

Adjustments to the LRLT orifices are based on the average volumetric flow,  $Q_m$ , provided by the pump  $P_1$ , as defined in Equation (11). Deviations of the flow rate through the orifice from  $Q_m$  change the characteristic impedance and introduce errors in estimating the flow rate, especially at higher frequencies [4]. Switching valves  $SV_{1,2}$  allow the device to operate in an oscillating or pulsating mode, where the pulsating mode superimposes the mean flow rate,  $Q_m$ , with the dynamic component,  $Q_c = A \cdot v$ . The volumetric flow rate derived from pressure measurements is compared to the experimental flow rate calculated as  $Q = Q_m + Q_c$  to validate the soft sensor.

$$\Delta p = \frac{Q_m \cdot \rho \cdot a}{2 \cdot A_{pipe}} \quad (11)$$

Figure 3 illustrates the implementation of the test rig design. Key elements are highlighted in the figure: the LRLT<sub>1,2</sub>, marked with red circles, are positioned at both ends of the measuring pipe (outlined in orange). The coupled cylinders, outlined in blue, are key in generating the dynamic flow rate by driving the oscillatory fluid motion.

Figure 3. Picture of the constructed test rig. [5]

#### 2.4. Test Cases

The first three test cases consider sinusoidally flow pulsations with frequencies of 5, 10, and 15 Hz, respectively. These tests were conducted under laminar flow conditions ( $Re < 2300$ ) for which the soft sensor has been previously validated [3]. This work investigates the impact of filtering the pressure transducer signals. All tests were carried out with a system pressure of 100 bar to minimize the compression effect for calculating the reference flow rate.

The last two test cases are pulsations with a frequency of 5 Hz. The difference from the first three test cases lies in the Reynolds number, which was chosen to be higher than the threshold of laminar flow. Therefore, the flow in these test cases was non-laminar. These test cases show the potential of the soft sensor in regions outside of laminar flow and thus broaden the validity range of the soft sensor. The five test cases are defined in Table 1.

A first-order low-pass filter with varying cut-off frequencies filtered each test case. For the laminar 5 Hz oscillation and the two turbulent test cases, the unfiltered data is shown, as well as the filtered data with cut-off frequencies of 100 Hz and one that is 1 Hz above the expected frequency. For example, for the case of 10 Hz oscillation, the cut-off frequency of the low-pass filter was set to 11 Hz.

Table 1. Parameters for each test case.

Test Case	Mean Volumetric Flow Rate $Q_{Stat}$ [l/min]	Reynolds Number $Re$ [-]	Frequency $f$ [Hz]	Temperature $T$ [°C]	Kinematic Viscosity $\nu$ [mm <sup>2</sup> /s]	Density $\rho$ [kg/m <sup>3</sup> ]

3. Results

3.1. Laminar Test Cases

Five test cases, three laminar and two non-laminar flows, were investigated. For each test, the calculated flow rate from the pressure transducers ("Soft Sensor") is compared to the measured signal from the test rig ("Test Rig"). For the case of laminar flow with a pressure oscillation of 5 Hz, the results are shown in the following three Figures (4 to 6). The three figures compare different filtering corner frequencies of the soft sensor to the measured flow rate. Figure 4 shows the unfiltered result of the soft sensor in comparison to the test rig. The effect of taking the derivative of the pressure signals during the calculation of the soft sensor can be seen in the deviation from the test rig flow rate.

Figure 4. Unfiltered flow rate compared to the test rig for a laminar 5 Hz pulsation.

This behavior is improved in Figures 5 and 6. Interestingly, a low-pass filter with a corner frequency of 100 Hz, as used in Figure 5, dramatically improves the soft sensor's result. The best result is obtained using a low-pass filter with a corner frequency of 6 Hz (1 Hz above the expected frequency), as seen in Figure 6.

Figure 5. Filtered flow rate (100 Hz cut-off).

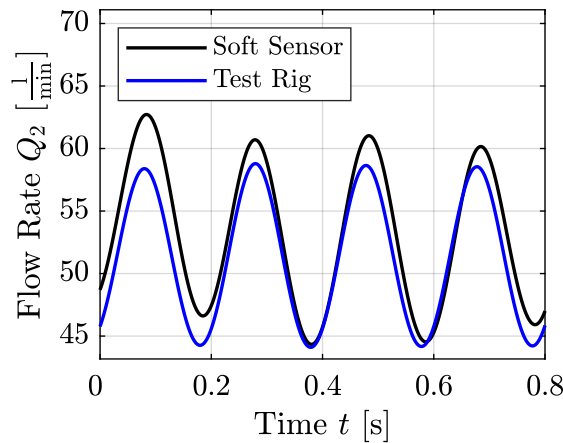

Figure 6. Filtered flow rate (6 Hz cut-off).

The next test case was a laminar flow with a pressure oscillation of 10 Hz. This time, presenting the unfiltered results is omitted due to redundancy to the first test case. Figure 7 and Figure 7 show that a 100 Hz low-pass filter yields accurate results, which can be further improved using a 11 Hz low-pass filter.

Figure 7. Filtered flow rate (100 Hz cut-off).

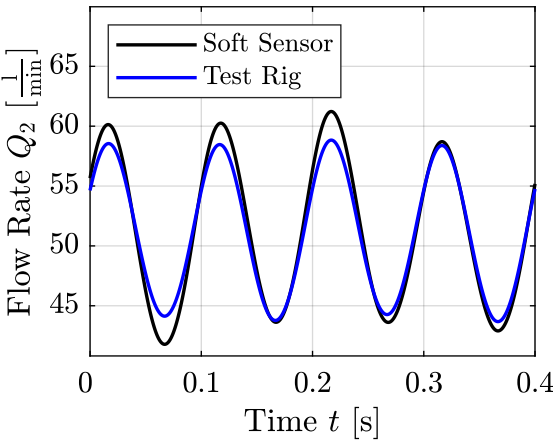

Figure 8. Filtered flow rate (11 Hz cut-off).

The third test case presented in this work is laminar flow with 15 Hz pressure oscillations. For this case, Figure 9 shows the filtering of the pressure signals with a 100 Hz low-pass filter, and Figure 10 filtering using a 16 Hz low-pass filter. Using the filter with a cut-off frequency closer to the expected frequency improved the result from the soft sensor. To sum up, the effect of basic filtering for the soft sensor can be observed for all three laminar test cases. Even filtering with 100 Hz improves the results greatly.

Figure 9. Filtered flow rate (100 Hz cut-off).

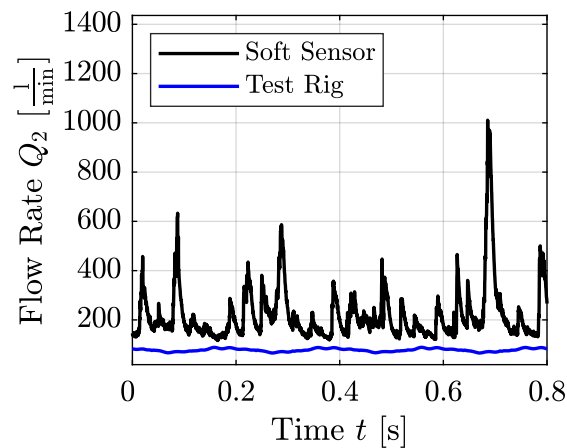

Figure 10. Filtered flow rate (16 Hz cut-off).

### 3.2. Non-Laminar Test Cases

The following two test cases are pulsation with a frequency of 5 Hz. Compared to the previously presented results, the flows are non-laminar due to their high Reynolds number  $Re = 3279$  and  $2703$ , respectively. These test cases are utilized to investigate the accuracy of the soft sensor for non-laminar flow and the impact of filtering on the measuring method. In Figure 11, the unfiltered volumetric flow rate of the soft sensor is shown. Like the laminar test cases, the flow rates do not match due to the high noise in the pressure derivatives. Compared to this result, applying a 100 Hz, shown in Figure 12, improves the results, and using a 6 Hz first-order Butterworth filter improves the results dramatically.

**Figure 11.** Unfiltered flow rate compared to the test rig for a non-laminar 5 Hz pulsation.

**Figure 12.** Filtered flow rate (100 Hz cut-off).

Figure 13. Filtered flow rate (6 Hz cut-off).

In contrast to the laminar test cases, a 100 Butterworth filter increases the accuracy, but suitable results are obtained by applying a filter with a cut-off frequency of 6 Hz. This finding is underlined in Figure 14 and 15, where a 100 filter does not suffice to match the test rig and soft sensor. However, suitable filtering with 6 Hz matches the test rig and soft sensor, as shown in Figure 15. For both test cases, the soft sensor can compute the transient volumetric flow rate accurately with a basic first-order Butterworth filter, demonstrating the soft sensor’s wide range of validity.

Figure 14. Filtered flow rate (100 Hz cut-off).

Figure 15. Filtered flow rate (6 Hz cut-off).

## 4. Discussion & Conclusion

This paper presents an innovative approach to transient flow measurement. It starts by reviewing methods and transient models. Then, it describes the analytical soft sensor, the experimental test rig, and the validation process using various test cases. The sensor provides accurate, real-time flow rate calculations even under challenging conditions with basic filtering of the pressure signals. This underlines the robustness of the soft sensor since no sophisticated filtering algorithm is required for accurate volumetric flow rate determination. Furthermore, the paper demonstrates that the soft sensor's range of validity extends beyond the laminar regime by showing its high accuracy for non-laminar transient flow.

The results indicate that basic filtering is essential to achieve reasonable measurement accuracy. Without filtering, unfiltered pressure signals as input to the soft sensor proved ineffective for both laminar and non-laminar flows. This is mainly due to the derivation of the pressure signals, which is utilized to compute the dynamic volumetric flow rate and is especially prone to error due to signal noise. In laminar flow test cases, a simple 100 Hz filter significantly improved the accuracy of measurements, bringing the results within an acceptable range. A 100 Hz filtering also demonstrated its value for non-laminar flows, though further refinement is necessary to achieve optimal results. In the validation, the investigated frequencies were known beforehand. However, in many applications like control, the frequency range is also known, which allows for the direct utilization of adequate filtering for the soft sensor. For applications where the frequencies might not be known, basic filtering of 100 Hz will increase the accuracy dramatically in most cases. Furthermore, for a more advanced approach, established methods such as the Fast Fourier Transform (FFT) can identify pulsation frequencies, enabling targeted filtering during operation. Therefore, no complicated preprocessing is necessary, underlining the robustness and easy-to-use nature of the soft sensor.

The findings demonstrate that the sensor effectively covers a broad range of Reynolds numbers, making it highly suitable for several fluid power applications. The results achieved in this initial study for non-laminar flows show promising accuracy. However, further investigation is essential, as the non-laminar regime includes transitional and turbulent flows. These flow types are notoriously challenging to describe, particularly when modeled physically. Consequently, mathematical models used in these scenarios are often either computationally intensive or inaccurate due to simplifications made. This underscores the importance of advancing the soft sensor's capabilities to address these complexities, ensuring its applicability to a broader range of fluid dynamics applications. Noteworthy is that most fluid power systems aim to operate in a laminar flow regime due to the increased power loss based on friction, which increases for non-laminar flows.

The results of the soft sensor under laminar and non-laminar flow conditions with basic filtering highlight its suitability for diverse industrial applications and represent a notable advance in soft sensors for transient volumetric flow rate determination. It shows particular promise in conditions monitoring and control, where the real-time and precise calculation of key system parameters is vital. Furthermore, the sensor's capability to monitor both pressure and flow rates facilitates the computation of hydraulic power, which can support predictive maintenance by providing deeper insights into the system's behavior. Unlike traditional numerical methods, which are often constrained to delivering either real-time results or high precision but not both simultaneously, this soft sensor overcomes such limitations, offering a balanced and efficient solution. Future work will focus on higher-frequency flows and the effects of reflections and different pressure profiles.

<i>f</i>	Frequency	[Hz]
<i>γ</i>	Propagation Operator	[-]
<i>I<sub>i</sub></i>	Modified Bessel function of the first kind of the <i>i</i> 'th order	[-]
<i>K</i>	Bulk Modulus	[Pa]
<i>K<sub>1</sub></i>	First part of the convolution integral	[-]
<i>K<sub>2</sub></i>	Second part of the convolution integral	[-]
<i>K<sub>1,app</sub></i>	Approximation of <i>K<sub>1</sub></i>	[-]
<i>k</i>	A Natural Number	[-]
<i>l</i>	Pipe section length	[m]
<i>L</i>	Length of the Pipe	[m]
<i>m</i>	Order of poles	[-]
<i>m<sub>i</sub></i>	Part of Assumed Weighting Function	[-]
<i>n<sub>i</sub></i>	Part of Assumed Weighting Function	[-]

$N$	Upper Limit of Residue Sum	[-]
$\Delta p$	Pressure Difference	[-]
$p_{Sys}$	System Pressure	[bar]
$p_1$	Pressure at Inlet	[bar]
$p_2$	Pressure at Outlet	[bar]
$Q$	Volumetric Flow Rate	[m <sup>3</sup> /s]
$Q_c$	Volumetric Flow Rate from the Cylinder	[m <sup>3</sup> /s]
$Q_m$	Mean Volumetric Flow Rate	[m <sup>3</sup> /s]
$Q_{max}$	Maximum Volumetric Flow Rate	[m <sup>3</sup> /s]
$Q_{min}$	Minimum Volumetric Flow Rate	[m <sup>3</sup> /s]
$Q_{Stat}$	Stationary Volumetric Flow Rate	[m <sup>3</sup> /s]
$Q_i$	Volumetric flow rate at Inlet: $i = 1$ and Outlet: $i = 2$	[m <sup>3</sup> /s]
$R$	Radius of the Pipe	[m]
$Re$	Reynolds Number	[-]
$R_H$	Hydraulic Resistance	[Pa/(m <sup>3</sup> /s)]
$s$	Laplace Variable	[-]
$\sinh_{approx}$	Approximation of the $\sinh(s)$ Function	[-]
$t$	Time	[s]
$t_n$	Normalized Time	[-]
$v$	Velocity of the Cylinder	[m/s]
$W_i$	Weighting function at End $i \in \{1, 2\}$ of the Pipe	[-]
$W'_i$	Weighting function at port $i \in \{1, 2\}$	[-]
$W_{i,dyn}$	Negative of $W'_{i,dyn}$	[-]
$W_{1,comp}$	Compressible Weighting Function at port 1	[-]
$W_{inc}$	Incompressible Weighting Function	[-]
$Wo$	Womersley Number	[-]
$z$	Number of Pistons of an Axial Piston Pump	[-]
$\alpha_D$	Discharge Coefficient	[-]
$\delta$	Degree of Non-uniformity	[-]
$\zeta$	Normalized Laplace Variable	[-]
$\zeta_k$	Poles of the Weighting Function	[Pas]
$Z_c$	Series impedance	[bar/(m <sup>3</sup> /s)]
$\eta$	Dynamic Viscosity	[Pas]
$\nu$	Kinematic Viscosity	[m <sup>2</sup> /s]
$\omega$	Pressure Variation Frequency	[1/s]
$\rho$	Fluid Density	[kg/m <sup>3</sup> ]
$\tau_n$	Normalized Time	[s]
