## Acknowledgements

Four years of experience studying and living in Germany provided me with an impressive journey in my life. Aachen is the city where I lived the longest since I have left my home when I was 19 years old. My academic career started in this city. I love this beautiful city although the sunshine is rare. Most importantly, there are a lot of people, whom I need to show my sincere thanks at the end of this important period of my life.

First and foremost, I would like to express my most sincere gratitude to my supervisor Prof. Ralf Littke. He gave me the opportunity to conduct my PhD study at the Institute of Geology and Geochemistry of Petroleum and Coal at the RWTH Aachen University. Prof. Littke devoted plenty of time and effort to propose new research ideas, revising my manuscripts and providing valuable advice and guidance through my PhD study. Prof. Littke has broad and profound knowledge which helped me expand my knowledge. In addition, Prof. Littke's rigorous attitude to science and his charming personality taught me how to become a qualified scientist and will inspire me in future studies and life.

I also would like to give my special words of thanks to Prof. Jan Schwarzbauer. He introduced me to work in the laboratory of organic geochemistry.

My special words of thanks should also go to Prof. Reinhard Sachsenhofer (Montanuniversität Leoben). He spent his precious time reviewing my thesis and accepted the task of being the co-examiner of my PhD.

Dr. Laura Zieger, Dr. Sebastian Grohmann and Dr. Reinhard Fink are highly appreciated because of their contributions to my publications. Impressive and intensive discussions with them help me improve my critical thinking as well as scientific writing.

Alireza Baniasad, and Dr. Garri Gaus are thanked for their professional instructions in geochemical and petrophysical experiments, respectively. Dr. Hannes Claes from the Institute of Clay and Interface Mineralogy at RWTH Aachen University is thanked for the XRD analysis.

I sincerely thank Patrick Thelen, a kind technician who was able to solve all kinds of laboratory and IT problems for me. I would like to acknowledge Donka Macherey for the help with sample preparation and Kerstin Windeck for the help with measurements. My heartfelt gratitude goes to Michelle Evertz for the assistance with respect to administrative work and to Annette Schneiderwind and Yvonne Esser for any help in the course of my laboratory work. Dr. Steffen Nolte is acknowledged for translating the abstract to German.

I would like to thank our Chinese colleagues, Tianyu Zheng, Zhongrui Wu and Zibing Zhao. Our friendship makes me feel warm and happy. Felix Froidl, Sebastian Amberg, Linda Burnaz, Ivana Jovancicevic, Nada Vidovic and Christina Schwanen are thanked for creating a friendly working environment.

My special thanks go to my former supervisor, Prof. Luofu Liu (China University of Petroleum, Beijing) for his endless support and encouragement in the past several years. Prof. Zhenxue Jiang, Prof.

Qun Luo and Dr. Chen Zhang, from China University of Petroleum, Beijing, are acknowledged for providing me samples for my thesis.

I gratefully acknowledge the funding from China Scholarship Council (CSC) for supporting my PhD study in Germany.

I deeply appreciate my mother and father. My parents have been providing unconditional care and love for decades. I sincerely appreciate my sisters for their support and understanding during my long-term study. They helped me take care of my parents while I was studying abroad. I would not have had the opportunity to complete a PhD abroad without my family. Love from my family is endless, selfless and great, and I will love all of them for the rest of my life.

## ABSTRACT

Source rocks are essential for both conventional and unconventional petroleum and gas resources. This thesis focuses on the characterization of non-marine source rocks covering a wide range of thermal maturity, from immature microbial gas source rocks to overmature source rocks.

In Chapter 2, source rock characterization was performed on 12 gas shale samples collected from Carboniferous Benxi and Permian Shanxi formations from the Yishan Slope of the Ordos Basin, China. These samples were interpreted with regard to mineral composition, thermal maturity, gas storage capacity as well as shale gas potential. The results reveal that the studied shales show low to moderate total organic carbon (TOC) content (0.1% to 2.3 %). Vitrinite reflectance ( $VR_r$ ) values of 2.3–3.0 % indicate an overmature stage with respect to oil generation. XRD data shows that clays are the major minerals (0–80%) followed by quartz (0–43%) in most samples. Due to their high abundance, clay minerals rather than organic matter control sorption capacity. However, compared to well-studied producing marine shale gas systems with higher TOC contents, the studied shales possess comparatively low gas storage capacities. Sorption has a negligible effect on gas production at pressures of > 10 MPa. This is important for deep reservoirs, where the pore pressure may be high.

In Chapter 3, a comprehensive petrographic and geochemical study was performed on 23 Triassic shale samples collected from 18 wells in the mid-western Ordos Basin. These Chang 7 Member samples were interpreted with regard to the thermal maturity and characteristics of organic matter (OM) as well as the paleo-depositional environment. The results reveal that the studied samples have moderate to very high TOC (0.2–24.8 %) and total sulfur (TS) contents (0.1–6.5 %). The good to very good hydrocarbon generation potential for most of the samples is proven by high  $S_1$  and  $S_2$  values (0.1–3.7 mg HC/g rock and 0.6–92.5 mg HC/g rock, respectively). Organic matter is mainly composed of type II to type III kerogen indicated by Rock-Eval data and supported by petrographical observations. It consists of a mixture of woody, terrigenous (mainly conifers) and aquatic OM. The studied member is a typical clay-rich source rock deposited in a sulphate-poor lacustrine to fluvio-deltaic environment under oxic to sub-oxic conditions. Low salinity is implied by different parameters such as TOC/TS ratios and molecular biomarker data.  $VR_r$  values (0.68–0.88%), average Rock-Eval  $T_{max}$  values (445 °C), biomarker parameters, and maturity indices based on aromatic compounds all indicate a thermal maturity within the oil window.

In Chapter 4, 30 Pleistocene source rocks from the central Qaidam Basin are described and discussed based on elemental data (TOC, TS, total inorganic carbon (TIC)), organic geochemical and organic petrographic analyses. These thick fine-grained rocks probably act as the main microbial gas source rocks in the region. Two different, lacustrine source rock facies have been identified based on the new data. Organic facies A samples with high TOC (4.1–25.3 %) and moderate TS content (1.5–3.7 %) were mainly deposited under a suboxic to anoxic freshwater column at the lake margins. Although this shallow water fluvial-lacustrine facies only occupies a small part of the whole sedimentary sequence, it has the highest hydrocarbon generation potential. In contrast, organic facies B

samples with low TOC (0.5–1.1 %) and TS contents (0.14–1.0 %) were deposited in more oxygen-rich brackish lake bodies. Rarely, anoxic conditions were present in sediments that were sealed by algal mats. Organic matter is composed of mixed type II-III kerogen derived mainly from aquatic plants. Organic facies A is interpreted to originate from abundant macrophytes (e.g. non-marine algae, submerged angiosperms) at the margin of the lake. In contrast, the OM in organic facies B is related to algae with some additional bacterial contribution. Terrestrial higher plants are subordinate in both organic facies. The cold and dry climatic conditions and very high burial rate favored microbial gas generation.

In chapter 5, the same sediments from the Tibetan Plateau (TP) region of NW China are presented based on other methods in order to obtain information on climate change, environmental conditions and weathering in the area of the Qaidam Basin. Here evidence from specific temperature-sensitive biomarkers (GDGTs), stable isotopes and concentrations of a large number of major and minor chemical elements of the Pleistocene Qigequan Formation was applied. The results confirm that two sediment types exist with completely different organic matter composition, i.e. organic facies A and B. The organic matter accumulation in both organic facies was primarily controlled by the palaeoredox conditions rather than palaeoproductivity. Furthermore, no significant differences between the GDGTs distributions in sediments is observed. Generally, the sediments were deposited under arid/cold conditions with weak chemical weathering, similar to the present-day situation. The Mean Annual Air Temperature was slightly higher than the present temperature. The  $R_{i/b}$  ( $\Sigma i\text{GDGTs}/\Sigma b\text{GDGTs}$ ) values are located between the higher modern  $R_{i/b}$  values and the lower Late Miocene  $R_{i/b}$  values, indicating neutral to alkaline soils conditions (pH varying between 6 and 10) and a continuous aridification process.

## ZUSAMMENFASSUNG

Muttergesteine sind sowohl für konventionelle als auch für unkonventionelle Erdöl- und Erdgasvorkommen von wesentlicher Bedeutung. Diese Dissertation befasst sich mit der Charakterisierung von nicht-marinen Ausgangsgesteinen, welche einen großen Bereich thermischer Reifen abdecken, von unreifen mikrobiellen Gasmuttergesteinen bis zu überreifen Muttergesteinen.

In Kapitel 2 wurden 12 Gasschieferproben aus den karbonischen Benxi- und permischen Shanxi-Formationen am Yishan-Hang des Ordos-Beckens in China untersucht. Diese Proben wurden im Hinblick auf die mineralische Zusammensetzung, die thermische Reife, die Gasspeicherkapazität und das Schiefergaspotenzial ausgewertet. Die Ergebnisse zeigen, dass die untersuchten Sedimentgesteine einen niedrigen bis mäßigen Gehalt an organischem Gesamtkohlenstoff (TOC) aufweisen (0.1% bis 2.3%). Vitrinitreflexionswerte ( $VR_r$ ) von 2.3-3.0% deuten auf ein überreifes Stadium in Bezug auf die Ölbildung hin. Die XRD-Daten zeigen, dass in den meisten Proben Tone die wichtigsten Mineralien sind (0-80%), gefolgt von Quarz (0-43%). Aufgrund ihres hohen Vorkommens dominieren eher Tonminerale die Sorptionskapazität statt des organischen Materials. Im Vergleich zu gut untersuchten, produzierenden, marinen Schiefergassystemen mit höheren TOC-Gehalten weisen die untersuchten Sedimentgesteine eine vergleichsweise geringe Gasspeicherkapazität auf. Bei Drücken von  $> 10$  MPa hat die Sorption einen vernachlässigbaren Einfluss auf die Gasproduktion. Dies ist wichtig für tiefe Lagerstätten, in denen der Porendruck hoch sein kann.

In Kapitel 3 wurde eine umfassende petrographische und geochemische Untersuchung von 23 triassischen Gesteinsproben durchgeführt, die aus 18 Bohrungen im mittleren bis westlichen Ordos-Becken entnommen wurden. Die Proben aus der Chang 7 Subformation wurden im Hinblick auf die thermische Reife und die Eigenschaften der organischen Materie (OM), sowie auf das Paläo-Ablagerungsmilieu interpretiert. Die Ergebnisse zeigen, dass die untersuchten Proben mäßige bis sehr hohe TOC (0.2-24.8%) und Gesamtschwefelgehalte (TS) (0.1-6.5%) aufweisen. Das gute bis sehr gute Kohlenwasserstoffbildungspotenzial der meisten Proben wird durch hohe  $S_1$ - und  $S_2$ -Werte belegt (0.1-3.7 mg HC/g Gestein bzw. 0.6-92.5 mg HC/g Gestein). Die organische Substanz besteht hauptsächlich aus Kerogen des Typs II bis III, wie aus den Rock-Eval-Daten hervorgeht und durch petrographische Beobachtungen bestätigt wird. Sie besteht aus einer Mischung aus holzigem, terrigenem (hauptsächlich Nadelbäume) und aquatischem OM. Die untersuchte Subformation ist ein typisches tonreiches Muttergestein, welches in einer sulfatarmen, lakustrinen bis fluvio-deltaischen Umgebung unter oxischen bis suboxischen Bedingungen abgelagert wurde. Verschiedene Parameter, wie das TOC/TS-Verhältnis und die molekulare Biomarkerdaten, belegen einen niedrigen Salzgehalt.  $VR_r$ -Werte (0.68-0.88%), durchschnittliche Rock-Eval- $T_{max}$ -Werte (445 °C), Biomarker-Parameter und Reifeindizes basierend auf aromatische Verbindungen weisen auf eine thermische Reife innerhalb des Ölfensters hin.

In Kapitel 4 werden 30 pleistozäne Muttergesteine aus dem zentralen Qaidam-Becken beschrieben und anhand von Elementardaten (TOC, TS, anorganischer Gesamtkohlenstoff (TIC)), organisch-geochemischen und organisch-petrographischen Analysen diskutiert. Die mächtigen, feinkörnigen

Gesteine sind wahrscheinlich die wichtigsten mikrobiellen Gasquellen in dieser Region. Auf Grundlage der neuen Daten wurden zwei unterschiedliche, lakustrine Muttergesteinsfazies identifiziert. Proben der organischen Fazies A mit hohem TOC (4.1-25.3%) und mäßigem TS-Gehalt (1.5-3.7%) wurden hauptsächlich unter einer suboxischen bis anoxischen Süßwassersäule an den Seeufern abgelagert. Obwohl diese Flachwasser-Fluvial-Lakustrin-Fazies nur einen kleinen Teil der gesamten Sedimentabfolge einnimmt, hat sie das größte Potenzial zur Bildung von Kohlenwasserstoffen. Im Gegensatz dazu wurden die Proben der organischen Fazies B mit niedrigen TOC- (0,5-1,1 %) und TS-Gehalten (0.14-1.0%) in sauerstoffreicheren Brackwasserseen abgelagert. Selten traten anoxische Bedingungen in Sedimenten auf, die dann durch Algenmatten versiegelt waren. Das organische Material besteht aus gemischtem Kerogen vom Typ II-III, welches hauptsächlich von Wasserpflanzen stammt. Es wird davon ausgegangen, dass die organische Fazies A von reichlich vorhandenen Makrophyten (z. B. nicht-marine Algen, submerse Angiospermen) am Rande des Sees stammt. Im Gegensatz dazu ist das OM in der organischen Fazies B auf Algen mit zusätzlichem bakteriellen Beitrag zurückzuführen. Terrestrische, höhere Pflanzen sind in beiden organischen Fazies untergeordnet. Die kalten und trockenen klimatischen Bedingungen und die sehr hohe Sedimentationsrate begünstigten die mikrobielle Gasbildung.

In Kapitel 5 werden dieselben Sedimente aus der Region des Tibetischen Plateaus (TP) im Nordwesten Chinas anhand anderer Methoden vorgestellt, um Informationen über den Klimawandel, die Umweltbedingungen und die Verwitterung im Gebiet des Qaidam-Beckens zu erhalten. Hierzu wurden Indikatoren aus spezifischen, temperatursensitiven Biomarkern (GDGTs), stabilen Isotopen und Konzentrationen einer großen Anzahl von chemischen Haupt- und Spurenelementen der pleistozänen Qigequan-Formation verwendet. Die Ergebnisse bestätigen, dass es zwei Sedimenttypen mit völlig unterschiedlicher Zusammensetzung der organischen Substanz gibt, nämlich die organische Fazies A und B. Die Anreicherung der organischen Substanz in beiden organischen Fazies wurde in erster Linie durch die Paläo-Redoxbedingungen und nicht durch die Paläo-Produktivität gesteuert. Weiterhin wurden keine signifikanten Unterschiede zwischen den GDGT-Verteilungen in den Sedimenten festgestellt. Im Allgemeinen wurden die Sedimente unter trockenen/kalten Bedingungen mit schwacher chemischer Verwitterung abgelagert, ähnlich wie in der gegenwärtigen Situation. Die mittlere Jahreslufttemperatur war etwas höher als die heutige Temperatur. Die  $R_{i/b}$ -Werte ( $\Sigma iGDGTs/\Sigma bGDGTs$ ) liegen zwischen den höheren modernen  $R_{i/b}$ -Werten und den niedrigeren spätmiozänen  $R_{i/b}$ -Werten, was auf neutrale bis alkalische Bodenbedingungen (pH-Wert zwischen 6 und 10) und einen kontinuierlichen Aridifizierungsprozess hindeutet.

Fig. 4.6	Relative proportions of (a) fluorene (FL), dibenzofuran (DBF), and dibenzothiophene (DBT), and (b) DBT/phenanthrene (P) ratio vs. total sulfur (TS). Note: symbols represent sample locations (see Fig. 4.1b).....	90
Fig. 4.7	$C_{30} \alpha\beta/(\alpha\beta + \beta\alpha + \beta\beta)$ vs. $C_{29} \alpha\beta/(\alpha\beta + \beta\alpha + \beta\beta)$ hopanes diagram, indicating maturity. Note: symbols represent sample locations (see Fig. 4.1b).....	92
Fig. 4.8	(a) Plots of total organic carbon (TOC) vs. $S_2$ indicating kerogen types and (b) TOC vs. volumetric percentage of OM indicating that most OM is well visible as macerals (see Fig. 4.3). Note: symbols represent sample locations (see Fig. 4.1b).....	93
Fig. 4.9	(a) TS vs. TOC, (b) tricyclic terpanes/ $C_{30}$ hopane vs. $C_{21}$ - $C_{22}$ steranes/ $C_{27}$ - $C_{29}$ steranes, and (c) homodrimane/drimane vs. gammacerane/ $C_{30}$ hopane. Note: symbols represent sample locations (see Fig. 4.1b).....	96
Fig. 4.10	(a) Ternary diagram showing the relative concentration of TOC, TS and Fe. (b) Pristane/ $n$ - $C_{17}$ vs. phytane/ $n$ - $C_{18}$ reflecting kerogen type, maturity, and depositional environment. Note: symbols represent sample locations (see Fig. 4.1b). Note: the different well symbols are related to the different locations.....	97
Fig. 5.1	(a) Schematic map showing the location of the Qaidam Basin in China, (b) its geological setting and sample well locations, and (c) cross sections in SE-NE and NW-SE directions (see b for position on the map). The dashed line with an arrow illustrates the depocenter shift during the depositional history of the basin (Qiu et al., 2013). Note: the different well symbols correspond to the different locations.....	108
Fig. 5.2	Generalized Pleistocene stratigraphic column for the study area (modified after Jian et al., 2013; Zhang et al., 2013a).....	110
Fig. 5.3	Major and trace elements normalized to Post-Archean Australian Shale (PAAS; Taylor and McLennan, 1985) for the Pleistocene source rocks.....	114
Fig. 5.4	Structures and molecular ion $m/z$ values for glycerol dialkyl glycerol tetraethers (GDGTs) (taken from Li et al., 2016).....	116
Fig. 5.5	The ternary diagram of the bGDGTs type I, II, III (data from De Jonge et al., 2014; Sinninghe Damsté et al., 2016; Crampton-Flood et al., 2021)....	119
Fig. 5.6	Fractional abundance of GDGT I–III GDGT 0–3, crenarchaeol, crenarchaeol', as fractions of the sum of all pictured GDGTs (bGDGTs as well as iGDGTs).....	119
Fig. 5.7	Typical $\delta^{13}C$ and C/N ranges for organic inputs (after Lamb et al., 2006). Note:	

	samples symbols represent sample locations (Fig. 5.1b).....	121
Fig. 5.8	(a) Sr/Ba and (b) Sr vs. CaO indicating palaeo-aslinity of the Pleistocene source rocks from the Qaidam Basin, China. Note: samples symbols represent sample locations (Fig. 5.1b).....	122
Fig. 5.9	(a) U/Th ratio vs. authigenic U to interpret paleo-redox conditions. (b) $U_{EF}$ vs. $Mo_{EF}$ (General patterns of $U_{EF}$ vs. $Mo_{EF}$ covariation is modified after Tribovillard et al. (2012)). (c) Comparison of TOC–Mo relationship between results of this study, Barnett Formation in the Fort Worth Basin and those of modern anoxic silled-basin environments (The TOC–Mo regression line slopes and previous studies data are given in Rowe et al. (2008). Note: the TOC contents used in Rowe et al. (2008) are original TOC <sub>o</sub> (TOC <sub>o</sub> = TOC <sub>meas</sub> /(1–0.363), so the slope for the Fort Worth Basin should be a little bit steeper). (d) Estimation of deep-water renewal time (years) during Pleistocene source rocks deposition using estimates from modern anoxic silled basins and the Barnett Formation in the Fort Worth Basin. Note: sample symbols represent sample locations (Fig. 1b). (e) TS/Fe vs. Al <sub>2</sub> O <sub>3</sub> /TOC and (f) TS/Mn vs. TiO <sub>2</sub> /TOC to interpret paleo-redox conditions (modified after Cichon-Pupienis, et al., 2020). Note: samples symbols represent sample locations (Fig. 5.1b).....	123
Fig. 5.10	Crossplot of the carbon isotopic composition of kerogen ( $\delta^{13}C_{org}$ ) vs. total organic carbon content (TOC). $\delta^{13}C_{org}$ shows a significant negative correlation with TOC in both facies A and B samples, indicating organic carbon deposition was controlled by redox conditions. Note: samples symbols represent sample locations (Fig. 5.1b).....	126
Fig. 5.11	(a) A–CN–K ternary diagrams for mudstones correction for K metasomatism is made by projecting data points back onto ideal weathering pathway from K-apex (Fedo et al., 1995). (b) Discrimination diagrams of SiO <sub>2</sub> vs. (Al <sub>2</sub> O <sub>3</sub> + K <sub>2</sub> O + Na <sub>2</sub> O) after Suttner and Dutta (1986) and (c) Ga/Rb vs. K <sub>2</sub> O/Al <sub>2</sub> O <sub>3</sub> (Roy and Roser, 2013) for the Pleistocene source rocks from the Qaidam Basin. (d) The distribution of soil sample GDGTs at low altitudes (<3,400 m asl) in the central Himalayas is characterized by high MBT and low $R_{i/b}$ values, opposite to the pattern observed for high altitudes (after Chen, et al.,2020). The characteristics of the MBT and high $R_{i/b}$ values for the studied samples are similar to those for higher altitudes. Note: samples symbols represent sample locations (Fig. 5.1b)....	128
Fig. 5.12	Sporopollen variations and implications for climatic conditions in the Quaidam Basin from Cai et al. (2012) with isotope data from (Lisiecki and Raymo, 2005	

	as shown in Cai et al., 2012). A/C: Artemisia/Chenopodiaceae; C+E: Xerophytic taxa (Chenopodiaceae+Ephedraceae) (%); ln(NAP/AP): ln ratios of Non Arboreal Pollen (NAP) to Arboreal Pollen; Thermophilic taxa: Betula+Quercus+Castanea+Juglans (%).....	129
Fig. 5.13	Comparison of reconstructed temperature based on soil calibrations in soils and lake sediments as listed from Eqs. 5.6 to 5.21.....	131
Fig. 6.1	Rock-Eval data on the Chang 7 member in the Ordos Basin: comparison of our results and other data from publications (see Chen et al., 2017).....	136
Fig. 6.2	Organic carbon accumulation rate in the microbial gas source rocks in the Qaidam Basin: comparison of our results and data on other data from publications.....	138
Fig. 6.3	CIA values for different source rocks in the Qaidam Basin from old (left) to young (right): comparison of our results and data on other data from Jian et al. (2013).....	139

## List of Tables

Table 1.1	Lake classification according to Carlsons trophic state index (Carlson and Simpson, 1996).....	3
Table 2.1	Total organic and inorganic carbon (TOC, TIC), total sulphur content (TS), vitrinite reflectance (VR <sub>r</sub> ), grain and bulk densities (ρ <sub>gr</sub> based on He-pycnometry and ρ <sub>b</sub> based on Archimedes), SPV (specific pore volume), for samples from well Quan 14.....	26
Table 2.2	Mineralogy based on XRD measurements. Qua – Quartz; Fel – Feldspar group kaolinite; Cal – Calcite; Dol/Ank – Dolomite/Ankerite; Siderite – Sid; Car – Carbonates (Cal + D/A + S); Kao – Kaolinite; Chl – Chlorite; I/S – Illite-smectite mixed layer; C – Clay minerals (Kao + Chl + I/S); Hal – Halite; Pyr – Pyrite; Ana – Anatase; Ver – Vermiculite; others (Hal + Pyr + Ana + Ver).....	26
Table 2.3	Results of porosity and methane high-pressure sorption measurements on shale samples from the Shanxi and Benxi formations (45 °C).....	29
Table 2.4	Results from high-pressure methane sorption measurements at 45 to 120 °C on four selected samples. ΔH and ΔS are molar enthalpy and entropy, respectively.....	31
Table 2.5	Value of Langmuir sorption capacity of individual clay minerals and isolated kerogen.....	34
Table A2.1	Gas storage capacities transformed into mol CH <sub>4</sub> /m <sup>3</sup> rock.....	41
Table 3.1	TOC, TIC, and TS data, as well as the three major primary sedimentary components calculated for the studied samples from the Chang 7 Member of the Midwestern Ordos Basin, China.....	47
Table 3.2	Rock-Eval pyrolysis data of the Chang 7 Member samples.....	51
Table 3.3	VR <sub>r</sub> values, maceral compositions (percentages based on whole rock samples), and minimum (min.), maximum (max.) as well as average (ø) diameters of pyrite framboids of the Chang 7 Member samples. Std = standard deviation, sk = skewness, n = number of framboids measured.....	52
Table 3.4	Biomarker parameters of acyclic alkanes of the source rocks from the Chang 7 Member. Pr = pristane; Ph = phytane; CPI = $2 \times \sum \text{odd } n\text{-C}_{23-29} / (\sum \text{even } n\text{-C}_{22-28} + \sum \text{even } n\text{-C}_{24-30})$ ; OEP = $(n\text{-C}_{21} + 6 \times n\text{-C}_{23} + n\text{-C}_{25}) / (4 \times n\text{-C}_{22} + 4 \times n\text{-C}_{24})$ ; WI = $\sum n\text{-C}_{21-31} / \sum n\text{-C}_{15-20}$ ; TAR = $(n\text{-C}_{27} + n\text{-C}_{29} + n\text{-C}_{31}) / (n\text{-C}_{15} + n\text{-C}_{17} + n\text{-C}_{19})$ ; P <sub>aq</sub> = $(n\text{-C}_{23} + n\text{-C}_{25}) / (n\text{-C}_{23} + n\text{-C}_{25} + n\text{-C}_{29} + n\text{-C}_{31})$ .....	55
Table 3.5	Biomarker parameters of tricyclic and tetracyclic terpanes, hopanes, and steranes of the source rocks from the Chang 7 Member in the mid-western Ordos Basin. Tri = tricyclic terpanes, Tet = tetracyclic terpanes, H = hopane, M = moretane, Gam = Gammacerane; HHI = homohopane index, steranes/hopanes = C <sub>27</sub> -C <sub>29</sub>	

	regular steranes/C <sub>29</sub> -C <sub>35</sub> 17 $\alpha$ -hopanes.....	57
Table 3.6	Parameters of the aromatic fractions and corresponding calculated vitrinite reflectances for the Chang 7 Member samples.....	59
Table A3.1	Identification of terpanes, steranes and aromatic compounds in Fig. 3.6.....	71
Table 4.1	Total organic (TOC) and inorganic carbon (TIC), total sulfur (TS), and Rock-Eval data with free hydrocarbons (S <sub>1</sub> ), hydrocarbon generation potential (S <sub>2</sub> ), temperature of the highest pyrolysis yield (T <sub>max</sub> ) and Hydrogen Index (HI).....	83
Table 4.2	TOC content, random huminite reflectance (VR <sub>r</sub> ) and maceral composition (percentages based on whole rock samples).....	84
Table 4.3	Ratios calculated from distributions of <i>n</i> -alkanes and acyclic isoprenoids.....	87
Table 4.4	Biomarker parameters in the aliphatic fraction.....	88
Table 4.5	Geochemical parameters in the aromatic fraction.....	91
Table 4.6	Age information (Zhang et al., 2013a), depth of the sampled wells and calculated linear sedimentation rates (LSR).....	98
Table 4.7	“Determined/calculated” average densities and different accumulation rates (AR) of the sampled intervals.....	99
Table A4.1	Identified terpanes and steranes as shown in Fig. 4.4.....	102
Table 5.1	Major and trace elements concentrations of the Pleistocene lacustrine mudstone .....	115
Table 5.2	Calculated elemental ratios of the Pleistocene lacustrine mudstones.....	116
Table 5.3	Isotopic, elemental* and Rock-Eval data of the kerogen from Pleistocene biogenic gas source rocks in the central Qaidam Basin, China.....	117
Table 5.4	Fractional abundance of <i>i</i> GDGTs and <i>b</i> GDGTs.....	120
Table 5.5	Related proxies based on <i>i</i> GDGTs and <i>b</i> GDGTs.....	120
Table 5.6	SPI calculated based on our studied wells.....	126
Table 5.7	Related calculated results based on <i>i</i> GDGTs and <i>b</i> GDGTs.....	129

## List of Abbreviations

EIA	U.S Energy Information Administration	C <sub>28</sub> ααα20S	24-Methyl-5α(H), 14α(H), 17α(H)-cholestane (20S)
XRD	X-ray diffraction	C <sub>28</sub> αββ20R	24-Methyl-5α(H), 14β(H), 17β(H)-cholestane (20R)
XRF	X-ray fluorescence	C <sub>28</sub> αββ20S	24-Methyl-5α(H), 14β(H), 17β(H)-cholestane (20S)
CAR	Carbonate content [wt.%]	C <sub>28</sub> ααα20R	24-Methyl-5α(H), 14α(H), 17α(H)-cholestane (20R)
SIL	Silicate content [wt.%]	C <sub>29</sub> ααα20S	24-Ethyl-5α(H), 14α(H), 17α(H)-cholestane (20S)
OM	Organic matter	C <sub>29</sub> αββ20R	24-Ethyl-5α(H), 14β(H), 17β(H)-cholestane (20R)
OM*	Organic matter content before sulfate reduction	C <sub>29</sub> αββ20S;	24-Ethyl-5α(H), 14β(H), 17β(H)-cholestane (20S)
TOC	Total organic carbon [wt.%]	C <sub>29</sub> ααα20R	24-Ethyl-5α(H), 14α(H), 17α(H) – cholestane (20R)
TC	Total carbon content	C <sub>29</sub> neoH	C <sub>29</sub> neohop-13(18)-ene
TIC	Total inorganic carbon	C <sub>30</sub> neo H	C <sub>30</sub> neohop-13(18)-enes
TS	Total sulfur	C <sub>30</sub> ββ H	C <sub>30</sub> 17β(H),21β(H)-hopane
S <sub>1</sub>	Free and absorbed hydrocarbons [mg HC /g rock]	C <sub>32</sub> ββ H	C <sub>32</sub> 17β(H),21β(H)-hopane
S <sub>2</sub>	Hydrocarbons generated from pyrolysis [mg HC /g rock]	C <sub>27</sub> β	C <sub>27</sub> 17β(H)-22,29,30-trinorhopane
S <sub>3</sub>	CO <sub>2</sub> generated from pyrolysis [mg CO <sub>2</sub> /g rock]	N	naphthalene
m <sub>d</sub>	Weight of the dry sample [kg]	2-MN	2-methylnaphthalene
m <sub>S</sub>	Immersed weights of the saturated samples indeionized water [kg]	1-MN	1-methylnaphthalene
m <sub>w-imm</sub>	Weight of the water-saturated sample immersed in water [kg]	BP	biphenyls
n <sub>∞</sub>	Maximum Langmuir capacity [mol/ kg]	2-EN	2-ethylnaphthalene
n <sub>excess</sub> (P,T)	Excess sorption amount [mol/ kg]	1-EN	1-ethylnaphthalene
P	Pressure [Pa]	2,6- + 2,7-DMN	2,6 + 2,7-dimethylnaphthalene
P <sub>L</sub> (T)	Langmuir pressure [Pa]	1,3- + 1,7-DMN	1,3 + 1,7-dimethylnaphthalene
T	Temperature [K]	1,6-DMN	1,6-dimethylnaphthalene
V <sub>bulk</sub>	Bulk volume [m <sup>3</sup> ]	1,4- + 2,3-DMN	1,4- + 2,3-dimethylnaphthalene
V <sub>p</sub>	Pore volume [m <sup>3</sup> ]	1,5-DMN	1,5-dimethylnaphthalene

$\rho_a$	Adsorbed gas densities [kg/m <sup>3</sup> ]	1,2-DMN	1,2-dimethylnaphthalene
$\rho_g(P,T)$	Free gas densities [kg/m <sup>3</sup> ]	2-MBP	2-methylbiphenyl
$\rho_b$	Bulk densities [kg/m <sup>3</sup> ]	DPM	Diphenylmethane
$m_w$	Saturated sample mass [kg]	3-MBP	3-methylbiphenyl
$\rho_w$	Density of deionized water at laboratory conditions [0.99 kg/m <sup>3</sup> ]	4-MBP	4-methylbiphenyl
$V_v$	Void volume [m <sup>3</sup> ]	DBF	Dibenzofuran
$\Delta S$	Molar entropy	1,3,7-TMN	1,3,7-trimethylnaphthalene
$P^0$	Pressure at the perfect-gas reference state [0.1 MPa]	1,3,6-TMN	1,3,6-trimethylnaphthalene
$n_{\text{excess}}$	Excess amount sorbed [mol/kg]	1,4,6- + 1,3,5-TMN	1,4,6- + 1,3,5-trimethylnaphthalene
$n_{\text{pore}}$	Gas storage capacities in pore [mol/kg]	2,3,6-TMN	2,3,6-trimethylnaphthalene
$n_{\text{sorbed}}$	Sorbed gas storage capacities [mol/kg]	1,2,7- + 1,6,7-TMN	1,2,7- + 1,6,7-trimethylnaphthalene
$m_{\text{excess}}$	Gibbs surface excess [kg]	1,2,6-TMN	1,2,6-trimethylnaphthalene
HI	Hydrogen index [mg HC /g TOC]	1,2,4-TMN	1,2,4-trimethylnaphthalene
OI	Oxygen index [mg CO <sub>2</sub> /g TOC]	1,2,5-TMN	1,2,5-trimethylnaphthalene
PI	Production index	1,2,3-TMN	1,2,3-trimethylnaphthalene
$T_{\text{max}}$	Temperature of maximum pyrolysis yield [°C]	1,3,5,7-TeMN	1,3,5,7-tetramethylnaphthalene
HC	Hydrocarbons	1,3,6,7-TeMN	1,3,6,7-tetramethylnaphthalene
ASE	Accelerated solvent extraction	1,4,6,7- + 1,2,4,6- + 1,2,4,7-TeMN	1,4,6,7- + 1,2,4,6- + 1,2,4,7-tetramethylnaphthalene
GC-FID	Gas chromatography-flame-ionization detector	1,2,5,7-TeMN	1,2,5,7-tetramethylnaphthalene
GC-MS	Gas chromatography-mass spectrometry	2,3,6,7-TeMN	2,3,6,7-tetramethylnaphthalene
HPHT	High-pressure/temperature manometric sorption set-up	1,2,6,7-TeMN	1,2,6,7-tetramethylnaphthalene
MS	Mass spectrometry	1,2,3,7-TeMN	1,2,3,7-tetramethylnaphthalene
SEM	Scanning electron microscope	1,2,3,6-TeMN	1,2,3,6-tetramethylnaphthalene
CPI	Carbon Preference Index	1,2,5,6- + 1,2,3,5-TeMN	1,2,5,6- + 1,2,3,5-tetramethylnaphthalene
DBT	Dibenzothiophene	DBT	Dibenzothiophene
GP	Generation potential	PHE	Phenanthrene
DCM	Dichloromethane	4-MDBT	4-methyldibenzothiophene
NSO	Nitrogen, sulphur and oxygen compounds	2 + 3-MDBT	2 + 3-methyldibenzothiophene
MN	Methylnaphthalene	1-MDBT	1-methyldibenzothiophene
MNR	Ratio of 2-methylnaphthalene/1-methylnaphthalene	3-MP	3-methylphenanthrene

MP	Methylphenanthrene	2-MP	2-methylphenanthrene
MPI	Methylphenanthrene index	9-MP	9-methylphenanthrene
OEP	Odd-even Predominance	1-MP	1-methylphenanthrene
Pr	Pristane	4,6-DMDBT	4,6-dimethyldibenzothiophene
Ph	Phytane	2,4-DMDBT	2,4-dimethyldibenzothiophene
PHE	Phenanthrene	2,6-DMDBT	2,6-dimethyldibenzothiophene
RC	Reference cell	3,6-DMDBT	3,6-dimethyldibenzothiophene
SC	Sample cell	2,7- + 3,7- + 2,8- DMDBT	2,7- + 3,7- + 2,8-dimethyldibenzothiophene
$\rho_{gr}$	Grain densities [kg/m <sup>3</sup> ]	1,4- + 1,6- + 1,8-DMDBT	1,4- + 1,6- + 1,8-dimethyldibenzothiophene
SPV	Specific pore volume [m <sup>3</sup> /kg]	1,3- + 3,4-DMDBT	1,3- + 3,4-dimethyldibenzothiophene
$\Delta H$	Molar enthalpy	1,7-DMDBT	1,7-dimethyldibenzothiophene
$Q_{st}$	Isosteric heat	2,3- + 1,9-DMDBT	2,3- + 1,9-dimethyldibenzothiophene
R	Molar gas constant [8.314 J/mol/K]	1,2-DMDBT	1,2-dimethyldibenzothiophene
$M_{CH_4}$	Molality of methane [mol/kg]	3-EP	3-ethylphenanthrene
$n_a$	Absolute gas storage capacity [mmol/g]	9 + 2 + 3,6-DMP	9 + 2 + 3,6-dimethylphenanthrene
$n_{free}$	Free gas storage capacity [mol/kg]	1-EP	1-ethylphenanthrene
$n_{total}$	Total gas storage capacities [mol/kg]	2,6 + 3,5-DMP	2,6 + 3,5-dimethylphenanthrene
$m_{transfer}$	Cumulative sum of the volume of the $V_r$ multiplied with the gas density difference in the RC before and after expansion into the SC [kg]	2,7-DMP	2,7-dimethylphenanthrene
$C_{19}Tri$	$C_{19}$ -tricyclic terpane	1,3 + 3,9 + 3,10 + 2,10-DMP	1,3 + 3,9 + 3,10 + 2,10-dimethylphenanthrene
$C_{20}Tri$	$C_{20}$ -tricyclic terpane	1,6 + 2,9 + 2,5-DMP	1,6 + 2,9 + 2,5-dimethylphenanthrene
$C_{21}Tri$	$C_{21}$ -tricyclic terpane	1,7-DMP	1,7-dimethylphenanthrene
$C_{22}Tri$	$C_{22}$ -tricyclic terpane	1,9 + 4,9 + 4,10-DMP	1,9 + 4,9 + 4,10-dimethylphenanthrene
$C_{23}Tri$	$C_{23}$ -tricyclic terpane	2,3-DMP	2,3-dimethylphenanthrene
$C_{24}Tri$	$C_{24}$ -tricyclic terpane	1,8-DMP	1,8-dimethylphenanthrene
$C_{25}Tri$	$C_{25}$ -tricyclic terpane	1,2-DMP	1,2-dimethylphenanthrene
$C_{24}TeT$	$C_{24}$ -tetracyclic terpane	TNR-1	trimethylnaphthalene ratio 1
$C_{26}Tri R$	$C_{26}$ -R tricyclic terpane	TNR-2	Trimethylnaphthalene ratio 2
$C_{26}Tri S$	$C_{26}$ -S tricyclic terpane	$VR_{TNR-2}$	Calculated reflectance from TNR-2
$C_{28}Tri R$	$C_{28}$ -R tricyclic terpane	TMNR	Trimethylnaphthalene ratio
$C_{28}Tri S$	$C_{28}$ -S tricyclic terpane	TeMNR-1:	Tetramethylnaphthalene ratio 1
$C_{29}Tri R$	$C_{29}$ -R tricyclic terpane	TeMNR-2	Tetramethylnaphthalene ratio 2

C <sub>29</sub> Tri S	C <sub>29</sub> -S tricyclic terpane	MPI-1	Methylphenanthrene index 1
Ts	18 $\alpha$ (H)-22,29,30-trisnorneohopane	VR <sub>MPI-1</sub>	Calculated reflectance from MPI-1
Tm	17 $\alpha$ (H)-22,29,30-trisnorhopane	MPDF	Methylphenanthrene distribution fraction
C <sub>29</sub> H	17 $\alpha$ (H), 21 $\beta$ (H)-30-norhopane	VR <sub>MPDF</sub>	Calculated reflectance from MPDF
C <sub>30</sub> *DH	15 $\alpha$ -methyl-17 $\alpha$ (H)-27-norhopane (diahopane)	MBPR	Methylbiphenyl ratio
C <sub>29</sub> M	17 $\beta$ (H), 21 $\alpha$ (H)-30-norhopane (normoretane)	MDR	Methyldibenzothiophene ratio
C <sub>30</sub> H	17 $\alpha$ (H), 21 $\beta$ (H)-hopane	VR <sub>MDR</sub>	Calculated reflectance from MDR
C <sub>30</sub> M	17 $\beta$ (H), 21 $\alpha$ (H)-hopane (moretane)	DMDR	Dimethyldibenzothiophene ratio
C <sub>31</sub> H S	17 $\alpha$ (H), 21 $\beta$ (H)-homohopane 30-homohopane (22S)	DMPR	Dimethylphenanthrene ratio
C <sub>31</sub> H R	17 $\alpha$ (H), 21 $\beta$ (H)-homohopane 30-homohopane (22R)	VR <sub>DMPR</sub>	Calculated reflectance from DMPR
Gam	Gammacerane	C <sub>29</sub> *H	C <sub>29</sub> 17 $\alpha$ (H),21 $\beta$ (H)-diahopane
C <sub>32</sub> H S	17 $\alpha$ (H), 21 $\beta$ (H)-30,31-dihomohopane (22S)	Ole	Oleanane
C <sub>32</sub> H R	17 $\alpha$ (H), 21 $\beta$ (H)-30,31-dihomohopane (22R)	C <sub>29</sub> $\beta\beta$ H	C <sub>29</sub> 17 $\beta$ (H),21 $\beta$ (H)-hopane
C <sub>33</sub> H S	17 $\alpha$ (H), 21 $\beta$ (H)-30,31,32-trishomohopane (22S)	C <sub>31</sub> $\beta\beta$ H	C <sub>31</sub> 17 $\beta$ (H),21 $\beta$ (H)-hopane
C <sub>33</sub> H R	17 $\alpha$ (H), 21 $\beta$ (H)-30,31,32-trishomohopane (22R)	C <sub>29</sub> N	C <sub>29</sub> 17 $\alpha$ (H),21 $\beta$ (H)-25-norhopanes
C <sub>34</sub> H S	17 $\alpha$ (H), 21 $\beta$ (H)-30,31,32,33-tetrahomohopane (22S)	SPI	Source potential index [t HC/m <sup>2</sup> ]
C <sub>34</sub> H R	17 $\alpha$ (H), 21 $\beta$ (H)-30,31,32,33-tetrahomohopane (22R)	MAAT	Mean annual air temperature
C <sub>35</sub> H S	17 $\alpha$ (H), 21 $\beta$ (H)-30,31,32,33,34-pentahomohopane (22S)	LST	Lake surface temperature
C <sub>35</sub> H R	17 $\alpha$ (H), 21 $\beta$ (H)-30,31,32,33,34-pentahomohopane (22R)	GDGT	Glycerol dialkyl glycerol tetraether
pregnane	5 $\alpha$ ,14 $\beta$ ,17 $\beta$ (H)-pregnane (diginane)	CIA	Chemical Index of Alteration
homopregnane	5 $\alpha$ ,14 $\beta$ ,17 $\beta$ (H)-homopregnane (20-methyldiginane)	SLST	Summer surface water temperature
C <sub>27</sub> $\beta\alpha$ dia20S	13 $\beta$ (H), 17 $\alpha$ (H)-diacholestane (20S)	WLST	Winter surface water temperature
C <sub>27</sub> $\beta\alpha$ dia20R	20R-13 $\beta$ (H), 17 $\alpha$ (H) - diacholestane	V <sub>r</sub>	Volume of the reference cell [m <sup>3</sup> ]

# 1 Introduction

## 1.1 Objectives

*Fig. 1.1. Principal Chinese oil-bearing basins showing the distribution of continental source rocks (modified after Powell, 1986).*

Organic matter (OM)-rich shales/mudstones are regarded as important hydrocarbon source rocks in basins. In the past few decades, source rocks have become also targets for unconventional shale-oil and shale-gas production in the world (Montgomery et al., 2005; Ross and Bustin, 2007 and 2009; Jarvie et al., 2007; Gasparik et al., 2014; Li et al., 2018; Qiao et al., 2020 and 2021a). Fine-grained sedimentary rocks, such as clayey siltstones, silty shales, siltstones, and shales, account for more than two-thirds of the world's sedimentary rocks and are formed via different processes in many environments (Stow, 1981; Land et al., 1997), but only a small amount of them is rich in OM. Two key conditions are required for OM-rich sediments to form: (1) surface water is rich in phytoplankton and microorganisms, (2) suitable sedimentary and diagenetic conditions exist for OM preservation and accumulation. As a result, these OM-rich sediments are typically deposited in anoxic sedimentary

environments within lakes, lagoons, eutrophic basins, closed embayments, or on a continental shelf below the wave base (Walteret, 1985; Land et al., 1997; Lemons and Chen, 1999).

In many areas of the world, there is a predominance of marine OM rich sediments, i.e. petroleum source rocks. However, OM-rich sediments in China are to a large extent of “transitional” (i.e. paralic) or continental origin (Zou et al., 2010). Since many OM-rich shales/mudstones have been found to be deposited in lake systems, the importance of lacustrine systems for the preservation of hydrocarbon prone OM has been recognized for many years. In China, the preponderance of large petroliferous intermountain basins, i.e., the site of extensive and long-existing lakes, provided the theoretical basis and impetus for the early development of the continental theory of hydrocarbon generation and accumulation (Huang et al., 1984; Zhai et al., 1984). The geographic and stratigraphic distribution of the principal Chinese oil-bearing basins is shown in Fig. 1.1. Compared to well studied marine OM-rich shales from other parts of the world, the non-marine sediments and their related resources in China are only basically understood, and also the geological conditions of different non-marine basins vary significantly. Thus, it is very important to study potential key factors determining the accumulation of OM in non-marine sediments. This thesis focuses on the OM-rich sediments collected from Paleozoic shales in the Yishan Slope of the southeastern Ordos Basin, the Mesozoic Yanchang Formation in the mid-western Ordos Basin and Cenozoic source rocks for microbial gas in the central Qaidam Basin China aiming to:

- i) characterize porosity and sorption capacity of thermally overmature Upper Paleozoic shales from the southeastern Ordos Basin in central China in the context of kerogen quantity, maturity and mineralogy, and furthermore to assess the shale gas potential of these shales;
- ii) reconstruct the depositional environments prevailing during deposition of the Chang 7 member and gain information on the biological precursors of its OM, quantify thermal maturity in the mid-western part of the Ordos Basin, for which almost no such information has been published so far;
- iii) evaluate the quality and quantity of kerogen in the Pleistocene lacustrine deposits in the central Qaidam Basin in northwest China and discuss the enrichment mechanism of OM as a basis for the exploration in the target area. In this context, also the terrestrial OM input needs to be considered. This study provides an example of an integrated approach using multiple proxies to analyze factors controlling OM accumulation in lacustrine environments;
- iv) specifically identify and quantify Pleistocene climate and weathering conditions based on elemental data, isotopes and temperature-sensitive biomarkers (GDGTs).

## 1.2 Characteristics of non-marine source rocks in China

According to Carlsons trophic state index, lake classification can be divided into seven types (Table 1.1). OM-rich sediments in marine basins are controlled by several factors, such as stratified water columns, nutrient supply and recycling, anoxic events, phytoplankton blooms, and rising sea levels

(MacIlvaine and Ross, 1973; Dean et al., 1985; Dimberline et al., 1990; Werne et al., 2002; Bradley, 2003; Macquaker et al., 2003, 2010a and b; Macquaker et al., 2010a; Schieber, 2011). Compared to marine settings, water circulation in lacustrine settings is usually less active, and deep-water overturning is easily inhibited (Fig. 1.2). The formation of OM-rich sediments in lacustrine environment is determined by water depth and stratification, and is improved by rapid burial events due to gravity flows and by addition of trace nutrients. In addition, lacustrine environments are more easily affected by external factors. For example, plenty of terrestrial or volcanic mineral input can dilute organic carbon accumulation but can also provide soluble micronutrients (iron, silicon, phosphorus) to promote algal blooms. Correspondingly, lacustrine OM-rich sediments have different depositional patterns and mechanisms in different basins. Their kerogen types and organic matter contents show large variation.

*Table 1.1. Lake classification according to Carlsons trophic state index (Carlson and Simpson, 1996).*

TSI	Attributes	Water Supply
<30	<b>Oligotrophy:</b> Clear water, oxygen throughout the year in the hypolimnion	Water may be suitable for an unfiltered water supply
30–40	Hypolimnia of shallower lakes may become anoxic	
40–50	<b>Mesotrophy:</b> Water moderately clear; increasing probability of hypolimnetic anoxia during summer	Iron, manganese, taste, and odour problems worsen. Raw water turbidity requires filtration
50–60	<b>Eutrophy:</b> Anoxic hypolimnia, macrophyte problems possible	
60–70	Blue-green algae dominate, algal scums and macrophyte problems	Episodes of severe taste and odour possible
70–80	<b>Hypereutrophy:</b> (light limited productivity). Dense algae and macrophytes	
>80	<b>Oligotrophy:</b> Clear water, oxygen throughout the year in the hypolimnion	Water may be suitable for an unfiltered water supply

One of the main conditions for the formation of lacustrine source rocks is that the lacustrine environment must have sufficient scale and duration to facilitate the accumulation of OM. Second, the tectonic environment must provide sufficient burial and thus maturation conditions for the generation of hydrocarbon (Powell, 1986). Actually, the second factor is not very important in some special environments. For example, the immature Pleistocene lacustrine source rocks in the Qaidam Basin generated the largest Quaternary microbial gas field in the world due to its special climate conditions, not requiring very deep burial.

Hutchinson (1957) recognised up to eleven types and some sub-types of lakes in the modern environment. However, only two categories seem to be related to the occurrence of source rocks. These are the alluvial lakes formed on humid flood plains and deltas, and the large tectonic lakes associated with epeirogenic movements. The physical and chemical processes of a lake system are deeply influenced by climate, the physical scale of the lake, and the energy of the river system that flows into the lake.

Fig. 1.2. Physical and biological processes affecting organic matter preservation in lakes (a) Schematic illustration of major sedimentological and bottom dynamic processes in lakes; (b) Processes affecting organic matter preservation in lakes (after Powell, 1986).

Modern lakes developed two modes of OM accumulation (Picard and High, 1981). The increase of OM in offshore sediments is due to sedimentation and preferential preservation under wave-base and hypoxic conditions. The OM accumulation in nearshore sediments is caused by the accumulation of plant remains. The deep anoxic lacustrine facies is characterized by OM-rich shale and marl deposited in the deep water environment under stratified lake conditions. OM is well preserved in anoxic bottom waters. There are also OM-rich sediments related to microbial mats and allochthonous organic debris from higher land plants. The lacustrine source rocks in tectonic lake basins are partly characterized by large thickness with some source rocks up to 700 m thick in China (Li et al., 1984).

Some Chinese authors, e.g. Tlian et al. (1983) and Huang et al. (1984) have categorised lacustrine source facies as well as their depositional setting as follows:

1). Freshwater lakes under humid climates

Subsidence and sedimentation are in equilibrium. The marshes are well developed and terrestrial higher plants flourished. Mudstone, coal, and oil shale alternate vertically, i.e. sedimentary facieses highly variable. These source rocks developed during the Jurassic and Late Triassic in the Ordos Basin and during the Jurassic in the Junggar Basin.

2). Fresh-brackish water lakes in semi-humid climates

The lakes are eutrophic and deep, but they get some OM from the land. The deep lacustrine source rocks are thick and interbedded with oil shale. Examples are the Early Cretaceous of Songliao and Jinqian basins.

3). Saline lakes in semi-arid climates

Black/blue OM-rich mudstones interbedded with thin salt beds, oil shales, and gypsum shales are widespread in the Paleogene, Neogene and Quaternary, e.g. Qaidam Basin. The source rock is formed in a semisalinity stage before salt precipitation.

4). Hypersaline lakes under arid climates

In a continuous saline lake, dark mudstone source rock interbedded with thick gypsum as well as salt beds formed. Examples are present in the Eocene and Oligocene of Jiangnan Basin.

The freshwater, brackish, and saline lake basins have different patterns of water column stratification (Picard, 1971). Freshwater lakes are generally formed in humid climates and their sediments are dominated by fine-grained sandstone, marlstone and siltstone. The kerogen formed in this type of lake is mainly sapropelic. Bradley (1964) suggested that the water cycle is interrupted in the deepest part of a seasonal freshwater lake, resulting in anoxic bottom water and the formation of thick layers of OM-rich sediments. Brackish and saline lakes are generally formed in dry continental states where debris and carbonate rocks are deposited and dolomitization is strong (Jiang, 1988; Deng and Qian, 1990). Saltwater lakes favor the preservation of OM because salinity-driven stratification tends to be more stable. Brackish lakes are usually connected to external fresh waters with limited water exchange and have a high rate of OM generation. However, these lakes lack reversal of bacterial activity and fragment dilution, which are crucial factors in the formation of OM-rich shales (Surdam and Stanley, 1979). Correspondingly, the OM-rich shales in different basins are controlled by different distribution patterns, sedimentary mechanisms, and OM origins (kerogen types). Thus, the exploration and development of resources in these different basins require different strategies.

The high total organic carbon (TOC) content of black mudstone/shale in deep lake basins can be explained by the water column stratification model. The water depth, oxygen-poor conditions and lake currents control the OM preservation and the distribution of organic-rich shales. In China, high quality lacustrine source rocks are usually associated with tuff beds formed by nearby volcanic eruptions. Volcanic ash is rich in soluble micronutrients (iron, silicon, phosphorus) that promote algal blooms.

Volcanic intercalations are associated with thicker high-quality source rocks. Saline/brackish lacustrine lake basins contain OM-rich dolomite mudstone, which formed mainly when the lake had high salinity, and the stratified water column deprived the underlying water of oxygen, thus preserving large amounts of OM. In summary, the lacustrine systems in China have good potential for oil and gas resources.

North China developed OM-rich shales deposited in marine-nonmarine transitional facies during Carboniferous-Permian periods. Such shales are typically fine-grained sediments deposited in near-shore, paralic environments including coastal marshes, deltas, tidal flats, bays and lagoons (Xiong et al., 2017; Yang et al., 2018). The OM in these shales is mainly originated from terrestrial higher plants in the adjacent depositional areas. The Carboniferous-Permian periods are key periods of geological evolution in China. The palaeogeographic environment changed greatly from marine facies to continental facies where a large number of transitional OM-rich shales was deposited. In North China, the transitional shales appear in the Carboniferous Benxi Formation (C<sub>2</sub>b) and the Permian Taiyuan (P<sub>1</sub>t) as well as Shanxi (P<sub>1</sub>sh) formations. In South China, the transitional shales were deposited in the Permian Liangshan (P<sub>1</sub>l) and Longtan (P<sub>3</sub>l) formations. These transitional shales are the most important source rocks in the Sichuan and Ordos basins feeding important gas fields (Zou et al., 2019 and Qiao et al., 2020).

After the Middle Triassic period, most of China has been an intracontinental sedimentary system, except the part of the Qinghai-Tibetan region. From Late Triassic to Cenozoic, the landscape features of several large inland lakes in the Ordos, Sichuan, Songliao, Bohai Bay, Qaidam, Junggar, Turpan-Hami and Tarim basins were obvious (Zou et al., 2019). The lacustrine OM-rich shales were mainly deposited in marsh and deep lake environments, where OM preservation and productivity are the most important controlling factors for the formation of OM-rich shales.

All in all, from Permian to Neogene, OM-rich lacustrine shales have been deposited in different freshwater to saltwater lacustrine environments in China.

### 1.3 Geology of the Ordos Basin

#### 1.3.1 Tectonic evolution

The Ordos Basin is an important basin containing coal, petroleum and gas, covering an area of  $26 \times 10^4$  km<sup>2</sup>. After the Indochina Movement, the tectonic evolution of China entered a new period, i.e. the marginal pacific tectonic domain and the Tethys tectonic domain evolved. The formation of the marginal pacific tectonic domain is the result of subduction of the Pacific Plate under the Asian Continent. The compression caused by the subduction divided the Paleo-North China Basin into an uplift in the east and the Ordos Basin in the west. The formation of the Tethys tectonic domain is the result of the subduction of the Tethyan oceanic or suboceanic crust under Eurasia. Tectonism caused by subduction not only formed the worldwide largest Indochinese fold area, but also formed large sedimentary basins such as the Sichuan, Ordos, Qaidam and Tarim basins in the margin area of Paleo-

Asian continent. Therefore, the Ordos Basin was the result of the combined action of the Pacific plate and the Tethys oceanic crust on the ancient Asian continent. Besides, based on the analysis of the thickness of Jurassic strata in the western margin of the basin, the Tethys tectonic domain seems to have a greater influence on it.

Fig. 1.3. Simplified tectonic map of China, showing major features discussed in the text and location of the Ordos basin (after Yang et al., 2005).

The present Ordos Basin is geographically located in the North China Block (Fig. 1.3), spanning the Shanxi, Shanxi, Ningxia and Gansu provinces as well as the Nei Monggol Autonomous Region. The North China Block includes several microblocks. Some scholars argued that these microblocks merged to form a craton or cratons at 2.5 Ga or earlier (Geng 1998; Zhang, 1998; Kusky et al., 2001, 2004 and 2006; Polat et al., 2005 a, b and 2006). However, some others argued that these microblocks did not merge until 1.8 Ga (Zhao et al., 2001a, 2005 and 2006; Liu et al., 2004 and 2006; Guo et al., 2005; Kröner et al., 2005 a and b). Nd  $T_{DM}$  models, the initial ratios of terrestrial igneous rocks appeared to lie on the same Nd isotope growth curve as chondritic meteorites (DePaolo and Wasserburg, 1976 a and b), indicate that the main crustal North China Block was formed between 2.9 and 2.7 Ga (Chen and Jahn 1998; Wu et al., 2003a and b).

The craton is separated by the Central Orogenic Belt and can be divided into the Eastern and Western Blocks (also referred to as the Ordos Block). Other blocks, such as the Alashan Block and Jiaoliao Block merged at the time of the collision of the Eastern and Western Blocks at 2.5 Ga. The Ordos Block is a stable part of the craton, with a thick mantle root, low heat flow, and little internal deformation after the Precambrian (Zhai and Liu, 2003). After that, the North China Block entered into an inactive tectonic stage from 2.2 to 1.85 Ga. About 1.9 – 1.8 Ga a granulite event indicates the continent–continent collision between the Ordos Block and Eastern Block (Zhao et al., 2001a, 2005, 2006; Wilde et al., 2003; Kröner et al., 2005a and b). Then there was an important metamorphic event from 1900 to 1800 Ma. So, all cratonic Precambrian rocks experienced the same metamorphic period of 1900-1800 Ma, with intrusion and mixing of crustal molten granite.

During the early Paleozoic, this area was part of the North China Plate. The north, west, and south sides were the Xingmeng and Qinqi troughs (Sun et al., 1989; Yue et al., 2001). During the early Late Paleozoic, the north and south margins of the North China Block experienced oceanic crust subduction and formed a Caledonian fold belt along a continental margin; this resulted in the uplift of North China Block and disappearance of the intraplate shallow sea basin. At the end of the Late Paleozoic, the North China Block began to subside, forming a graben-like inland epeiric sea basin bounding by the Caledonian fold belt in the north and south and connecting with the Qilian Sea. The Qilian Sea on the west side combined with the fold belts on the north and south sides controlled the sedimentary types and accumulation characteristics of the Ordos Basin in the Late Paleozoic. During the Triassic, the basin basically inherited the tectonic framework at the end of the Late Paleozoic. Under the control of sedimentation, the Triassic coal-bearing strata were deposited in Zichang and Hengshan areas. Under the influence of oceanic crust subduction of the Tethys tectonic domain, the western and southwestern margins were strongly uplifted, which made the area become a part of a large dustpan-like inland basin surrounded by folded orogenic belts on the north, west and south sides. The Indosinian movement at the end of Triassic caused the uplift of the whole region, then subjected to denudation and deformation, which turned into a relatively stable depression stage after the Early Jurassic, when the Ordos Basin was formed.

The last stage of Ordos Basin evolution occurred at the Early Cretaceous (Zhao et al., 2011). A large part of the basin received sediment during this period. Since the Late Cretaceous, the basin experienced a uniform, extensive uplift and denudation, resulting in the extensive denudation of Cenozoic strata except for the Neogene red clay and Quaternary loess deposits. During Eocene and Oligocene stages, the disintegration of the Ordos Basin (or block) began to occur, resulting in uplift in source areas and enlargement in depositing thickness and range of sediments. During the early to middle Miocene periods, the uplift area was mainly distributed in all tectonic units except for the Yishan Slope. The eastern part of the Shanbei was uplifted obviously, and the uplift rate is much higher there than in the western part. From the late Miocene to Pliocene period, in the south and east of the basin red clay sediments were widely deposited with large extension and thickness.

During the Quaternary, the basin, due to the south-north compressive stress, has experienced subsidence, uplift, depression and uniform uplift, in turn, before disintegration of the paraplain at an early age. The main river systems of the Loess Plateau, as well as the Yellow River, were formed during 1.67-1.45 Ma. During the middle Quaternary period, structural activities were more frequent, resulting in the main drainage direction of NNW and NW. In the Later Quaternary period, rivers cut downward and the topography gradually formed reaching that of today.

### 1.3.2 Sedimentary fill

The North China Block includes a large area of locally well-exposed Archaean crust, including c. 3.8-2.5 Ga gneiss, tonalite-trondhjemite-granodiorite (TTG), mica schist, graphite- and sillimanite-bearing gneiss (khondalite), migmatite, granite, ultramafic bodies, amphibolite, banded iron formation (BIF), dolomitic marble, and meta-arkose (Jahn and Zhang, 1984 a and b; Jahn et al., 1987; Bai, 1996; Wang, 1991; Wang and Zhang, 1995; Wang et al., 1997). The Archaean rocks are overlain by conglomerates, quartzites, shales, sandstones, and carbonates of the 1.85-1.40 Ga Mesoproterozoic Great Wall (Changcheng) Series (Li et al., 2000a and b). In some central areas of the North China Block, 2.40-1.90 Ga Palaeoproterozoic sequences deposited in cratonic graben are preserved (Kusky and Li, 2003).

The Late Archaean Qinglong foreland basin and fold-thrust belt are now preserved as several remnant folded sequences (Kusky and Li, 2003; Li and Kusky, 2006). From bottom to top, the sediments can be divided into three subgroups. The lower subgroup, which is composed of quartzite-mudstone-marble, is well preserved in central sections of the Qinglong foreland basin. The middle subgroup and upper subgroup are graded turbidite- and molasse-type sediments, respectively. The western edge of the Qinglong Foreland Basin is strongly affected by thrust folds, and is overthrust by active marginal rocks. The eastern margin of the Qinglong Foreland Basin has less deformation.

During the early Paleozoic period, the North China block tidal-flat and shallow-marine sediments were deposited including oomicrites, minor clastic rocks, and dolomites with a thickness of around 300–600 m in the main area of the basin (Sun et al., 1989).

During the Carboniferous, a transgression occurred on the North China Block. In the middle and eastern parts of the Ordos Basin, a tidal-flat environment developed during the deposition of the Carboniferous Benxi Formation. The depositional environment of the Carboniferous Taiyuan Formation was shallow marine resulting in extensive tidal-flat facies with limited deltaic sand bodies in the northern area of the basin (Fu et al., 2003). The Taiyuan Formation developed black shales interbedded with carbonates, sandstones, and coals with a thickness of about 22–276 m (Yang et al., 2005). During the Early Permian period, the basin received shallow lacustrine and extensive delta sediments (Fu et al., 2003). The Lower Permian succession consists of the Shanxi (37–125 m) and Xiashihezi (100–200 m) formations, which developed swamp and shallow-lacustrine mudstones interbedded with coals and fluvio deltaic sandstones interbedded with mudstones in the central and southern areas and the northern area of the basin, respectively. A small number of marine carbonate

rocks and fossils were found in the Lower Permian in the southern area of the basin (Tian and Zhang, 1997), indicating a small-scale transgression. During the Upper Permian–Middle Triassic period, the basin mainly developed red deltaic, fluvial, and shallow-lacustrine clastic rocks under an arid climate (Zhai, 1990). The Early–Middle Triassic strata in the southwestern part of the Ordos Basin experienced the transgression of the Songpan-Ganzi residual ocean basin, which is characterized by thin layers of shallow marine sandstone, mudstone and carbonate rocks containing marine fossil debris (Zhang, 1997).

Fig. 1.4. Stratigraphic columns, depositional environments, and source-reservoir-seal associations in the Ordos basin (A) for the Lower Ordovician–Upper Permian; (B) for the Upper Triassic–Lower Jurassic (after Yang et al., 2005).

In the Late Triassic, the Ordos Basin developed the southwest fan delta and the northern delta. The clastic wedges deposited in the southwestern foreland depression of the Ordos Basin are more than 3,000 m thick and gradually tapering to 1000 m to the east (Li et al., 1995). The upper Yanchang Formation was deposited under extensive shallow lacustrine lake and swamp environments with a thickness of around 100 m.

The Fuxian Formation of the Lower Jurassic was formed on the erosion surface of the pre-Jurassic. It mainly consist of conglomerate and sandstone of the incised braided channel system (Wu and Xue, 1992). The lower section of the Yanan Formation is mainly composed of sandstones deposited in the incised valleys, and then the meandering river point bars were directly deposited on the erosive terrace (Wu and Xue, 1992). The upper section of the Yanan Formation was deposited in marsh and extensive shallow lake environments with a thickness of around 40-90 m.

The lower and middle sections of the Middle Jurassic mainly consists of fluvial, coarse-grained feldspar-bearing sandstones, while the upper part consists of lacustrine mudstones, with a thickness of about 300-500 m (Guo et al., 1994). Most areas of the Ordos Basin show limited and thin Upper Jurassic deposits (Zhai, 1990). The Lower Cretaceous consists of fluvial and lacustrine sediments with a thickness of 200-1000 m (Sun et al., 1989) (Fig. 1.4).

The Paleogene composes of only the Qingshuiying Formation distributed in the western Ordos Basin and has unconformable contact with the underlying parallel formations. The Miocene Baode Formation, Pliocene Jingle Formation and Quaternary sediments are widely distributed in the Ordos Basin.

## 1.4 Geology of the Qaidam Basin

### 1.4.1 Tectonic evolution

The Qaidam Basin is part of a basin-range system that is located at the northern edge of the Tibetan Plateau covering an area of around 120,000 km<sup>2</sup>, with an altitude up to 2.7–3.5 km above sea level (Fig. 1.5). During the Paleoproterozoic, the continental nucleus including the Yangtze, North China, and Tarim cratons were formed, except for the Qinghai-Tibetan Plateau. The basement of the Qaidam Basin formed during Meso- to Neoproterozoic in relation to the ocean–continent transition during the Mesoarchean to Proterozoic and the post-Cryogenian rift. After that, the thick platform cover formed, i.e. clastic sedimentation and carbonate platform formed a stable crustal tectonic unit.

The Mesozoic and Cenozoic tectonic evolution of the Qaidam Basin can be divided into three tectonic-sedimentary stages: (1) piedmont fault depression stage in the Mesozoic; (2) unified depression stage from Paleogene to Neogene; and (3) subsiding depression in the east and cyclic folding in the center and west during the Quaternary based on the comprehensive analysis of regional tectonic setting, tectonic movement, unconformities, stratigraphic distribution, sedimentary characteristics and tectonic evolution history.

#### 1. Piedmont fault depression stage in the Mesozoic.

In the Early Jurassic, the basin was formed in the interior of the Qaidam Block. During the early and middle Jurassic (after the Indosinian Movement and before the collage of the Gangdise block and Eurasia), the whole northwest region of China including the Qaidam Basin was affected by intense extensional tectonics. During this period, the Qaidam Basin was in an extensional tectonic setting,

related to the Late Indosinian period. The early Yanshanian tectonic event in the Middle Jurassic led to the first tectonic inversion. After that, the basin entered into the stage of compression and uplift.

Fig. 1.5. Regional tectonic outline of the northern part of Qinghai-Tibet Plateau, showing current relationship between the Qaidam Basin and neighbouring Altyn Tagh Fault and Tarim Basin (after Zhou et al., 2006). ATF, Altyn Tagh Fault; RXF, Ruoqiang-Xingxingxia Fault; NATS, Northern Altyn Tagh Suture; NCB, North China Block; SCB, South China Block; S, suture; T, terrane.

## 2. Cretaceous compression and uplift stage

During the Late Cretaceous, Central Asia including the Qaidam Basin did not receive much sediment, suggesting that Central Asia was a vast plateau during this period and the Qaidam Basin entered the stage of compression and uplift. Due to the continuous northward movement of the Indian Plate and intracontinental subduction during Paleogene, the Qaidam Basin was in a compression stage. During Oligocene (Upper Ganchaigou Stage) and early Miocene (Lower Youshashan Stage), compression continued with the intensification of intracontinental subduction of the Tibetan Plateau.

## 3. Subsiding depression in the east and cyclic folding in the center and west during the Quaternary.

During the Middle and Late Himalayas periods, the intracontinental subduction of the Tibetan Plateau was further intensified, and the basin was further squeezed. During the Late Himalaya-Neotectonic Movement, the western and northern Qaidam Basin was affected by strong tectonic activities, resulting in a large number of folds and faults. The central and eastern Qaidam Basin further subsided under the influence of compression, and the Quaternary subsidence center migrated to the Sanhu area.

### 1.4.2 Sedimentary fill

Fig. 1.6. Stratigraphic division, lithology, and source rocks in the Qaidam Basin (changed after Guo et al., 2017).

The Qaidam Basin is filled with Mesozoic–Cenozoic sediments with a thickness of more than 16,000 m originating from the surrounding mountains. All sediments developed on the top of the pre-Mesozoic basement comprising igneous and metamorphic rocks (Fig. 1.6). The Mesozoic deposits in the basin include the Jurassic System and Cretaceous System (Quanyagou Formation). From the bottom

to the up, the Jurassic System can be divided into the Xiaomeigou Formation ( $J_1$ ) of the Lower Jurassic, the Dameigou Formation ( $J_2$ ) of the Middle Jurassic, and the Caishiling and Hongshuigou formations ( $J_3$ ) of the Upper Jurassic (Fig. 1.6). The Lower Jurassic sediments are mainly distributed in the western segment of the northern margin of the Qaidam Basin and the intersection area of the Qilian Mountains and the Altun Mountains, with a distribution area of 22,000 km<sup>2</sup> and a maximum thickness of 2,200 m. The deposition centers were located at Kunte Yi, Yibei and Lenghu areas. The north-west spreading Yibei fault depression and Kunteyi fault depression were connected, with an area of 5,400 km<sup>2</sup> and a maximum thickness of 2,000 m. Renghu fault depression is nearly north-south spreading, with an area of 600 km<sup>2</sup> and a maximum thickness of 2,200 m. During the Middle Jurassic, the sedimentary range migrated eastward and extended to the front of the Qilian Mountains. The Delingha Sag in the eastern part of the basin covers an area of 9,600 km<sup>2</sup> with a maximum thickness of 900 m. Due to the influence of the late tectonic movement, the southern strata in the western area of the northern margin of the Qaidam Basin suffered serious denudation. The Middle Jurassic sediments are mainly distributed along with the Saishiteng-Yuka, covering an area of 4,200 km<sup>2</sup>, and the thickest area was located in the Yuka area with 800 m. From Late Jurassic to Early Cretaceous, a set of red molasse deposits dominated by alluvial-fluvial, littoral and shallow lacustrine facies was formed under the control of arid palaeoclimate, which was the product of the compression-depression evolution of the basin. From Late Jurassic to Early Cretaceous, the sediments range was relatively large compared to that in Early Jurassic and Middle Jurassic, which is characterized by gradually expanding from the western and northwestern margins of the basin to the inner basin.

Cenozoic sedimentation began in Paleocene and was synchronized with the India-Asia collision. From the bottom to the top strata, the Cenozoic sediments can be divided into Lulehe Formation ( $E_{1+2}$ ), the lower member of the lower Ganchaigou Formation ( $E_{31}$ ), the upper member of the lower Ganchaigou Formation ( $E_{32}$ ), the upper Ganchaigou Formation ( $N_1$ ), the lower Youshashan Formation ( $N_{21}$ ), the upper Youshashan Formation ( $N_{22}$ ), the Shizigou Formation ( $N_{23}$ ), and the Quaternary Qigequan Formation ( $Q_{1+2}$ ). The  $E_{1+2}$  and  $E_{31}$  formations were deposited in the early filling stage before the weak depression stage, which consists of a set of coarse-grained to fine-grained brown-red and brown sandstone and mudstone.  $E_{32}$  Formation was deposited during the depression stage. The main depression was located in Mangya sag and Yiliping sag. The distribution center of the  $N_1$  and  $N_{21}$  formations is located at Yiliping depression. The basin is distributed in a rhomb-shape. The regional unconformities at the bottom of the  $N_{22}$  Formation are widely distributed in the periphery of the basin, and the strata under it were strongly denudated. This stage is the strike-slip thrust deformation stage of the basin, and the thrust is mainly caused by the south-side compression. As a result, dextral strike-slip occurred in the west of the basin, and a series of linear structural belts were formed. These linear structural belts first developed in the western part of the basin, and then gradually extended to the eastern part of the basin, resulting in the subsidence of the whole basin and the gradual eastward migration of the sedimentary center. The  $N_{23}$  Formation was deposited during the period of lake level decline. During

this period, the lake area was the smallest and the water body was generally shallow. The fluvial inundation facies is widely distributed in the basin, while the normal lacustrine facies is limited and distributed in the Sanhu area and Yiliping area in the east of the basin. During the Quaternary, the Qaidam Basin developed a large, shallow, saltwater lake with no obvious topographic break. The Quaternary Qaidam Basin is a typical inland mountain basin without outlets. The Quaternary strata are unconformably overlying Neogene strata with a maximum thickness of more than 3 km. The sedimentary characteristics record the process of lake development and climate change from humid to dry.

## 1.5 Chapter overview

This thesis consists of a general introduction, three main chapters and a general outlook chapter listed as follows:

**Chapter 2:** *Controls on gas storage characteristics of Upper Paleozoic shales from the southeastern Ordos Basin.*

This chapter mainly comprises of elemental analyses, organic petrography, XRD and petrophysical information on the Upper Paleozoic shales in the Southern Ordos Basin, which provides insights on the porosity and sorption capacity of these shales in the context of kerogen quantity, thermal maturity and mineralogy. The results of this study can be used to assess shale gas potential of these rocks under variable temperature and pressure conditions. It was published in the “Marine and Petroleum Geology” in 2020.

**Chapter 3:** *Paleo-depositional environment, origin and characteristics of organic matter of the Triassic Chang 7 Member of the Yanchang Formation throughout the mid-western part of the Ordos Basin, China.*

This chapter contains primarily organic petrography, carbon and sulfur contents, Rock-Eval pyrolysis and molecular organic geochemistry on aliphatic and aromatic hydrocarbons results from 23 clay-rich source rocks samples collected from 18 wells located in mid-western part of the Ordos Basin, China, to i) reconstruct the depositional environments prevailing during deposition of the Chang 7 member and gain information on the biological precursors of its OM and ii) to quantify thermal maturity. It was published in the “International Journal of Coal Geology” in 2021.

**Chapter 4:** *High microbial gas potential of Pleistocene lacustrine deposits in the central Qaidam Basin.*

This chapter investigates the interpretation of elemental data on organic and inorganic carbon as well as total sulfur, organic geochemical and organic petrographic analysis of Pleistocene source rocks in the central Qaidam Basin. The quality and quantity of kerogen in the source rocks have been evaluated and the enrichment mechanism of OM as a basis for the exploration in the target area is discussed. In this context, also the terrestrial OM input needs to be considered. This study documents a

case for such depositional settings and provides an example of an integrated approach using multiple proxies to analyze factors controlling OM accumulation in lacustrine environments. It was published in the “International Journal of Coal Geology” in 2021.

**Chapter 5:** *Climatic conditions during the Pleistocene in the Central Qaidam Basin, NE Tibetan Plateau: Evidence from GDGTs, stable isotopes and elements of the Qigequan Formation.*

This chapter investigates the interpretation of GDGTs, stable isotopes and chemical elements of Pleistocene sediments in the central Qaidam Basin. The origin of organic matter and GDGTs, as well as depositional environments were analyzed and the controlling factors of the OM accumulation in the target area are discussed. In addition, the paleo-climate conditions of the Tibetan Plateau during the Pleistocene were interpreted. This study fills a gap in the climate research of the Tibetan Plateau. The characteristics of the Pleistocene GDGTs are analyzed for the first time. It will be submitted to a journal in 2021.

## **2 Controls on gas storage characteristics of Upper Paleozoic shales from the southeastern Ordos Basin.**

### **2.1 Abstract**

Potential shale gas resources in China are not only of marine but also of marine-terrigenous transitional and continental origins. To analyze the controls on gas storage capacity of shales from the Carboniferous Benxi and Permian Shanxi formations, high-pressure/temperature methane sorption isotherms (up to 25 MPa and 120 °C) and porosity have been measured on 12 samples from the Yishan slope. Total organic carbon (TOC) content of Shanxi and Benxi shales are low to moderate from 0.1% to < 2.3%. All samples have reached the over-mature stage as indicated by vitrinite reflectance values between 2.35% and 2.97% and show lithologic variation where clays are the major minerals (0%–80%) followed by quartz (0%–43%) in most samples. The largest fraction of gas (> 80%) is stored on clay minerals (illite/smectite mixed layer and kaolinite) controlling both sorption capacity and porosity. TOC content, due to its low values, is of minor importance. Benxi and Shanxi shales possess comparatively low gas storage capacities compared to producing marine shale gas systems. Combined with the large amount of clay minerals that make hydraulic fracturing more difficult they are regarded unfavourable for shale gas exploitation. Although a substantial amount of gas can be stored sorbed in excess of the free gas in gas shales, methane sorption has a negligible effect on gas production at pressures above 10 MPa. This has major implications for deep reservoirs where pore pressures in the matrix may not be reduced sufficiently before production ceases.

### **2.2 Introduction**

Compared to crude oil and coal, natural gas produces less carbon dioxide upon combustion and is regarded as an ecologically more favorable fossil fuel. Thus, exploration for and research on shale gas reservoirs became more important during the last two decades and has expanded from marine (Montgomery et al., 2005; Ross and Bustin, 2007, 2009; Jarvie et al., 2007; Gasparik et al., 2014) to terrestrial (Katz and Lin, 2014; Merkel et al., 2016) and marine-terrigenous transitional (herein called “transitional”) shales. Such shales are typically fine-grained sediments deposited in near-shore, paralic environments including coastal marshes, deltas, tidal flats, bays and lagoons (Xiong et al., 2017; Yang et al., 2018). Gas storage in these rocks depends on thermal maturity, type and quantity of organic matter (OM), but also on source rock properties such as lithology-dependent petrophysical characteristics like porosity, pore size distribution and sorption capacity (Chalmers and Bustin, 2007; Bustin et al., 2008; Ross and Bustin, 2007, 2009; Ji et al., 2012; Zhang et al., 2012; Yang et al., 2015; Fink et al., 2018).

Fig. 2.1. Schematic map showing the location of the Ordos Basin (a), study area (b, the Upper Paleozoic Gas field modified after Yang et al. (2016) and Wu et al. (2017)), sampled well (c, after Xiong et al. (2017)) and a transect (d, modified after Yu et al. (2017)).

In the United States, natural gas production from fine grained rocks, rich in overmature kerogen increased dramatically over the last decade; now more than half of total gas production is derived from such rocks (EIA, 2019, 2020). Usually, the term “shale” is applied, although these rock's lithologies

range from carbonates to siliceous shales (Bustin et al., 2008; Uffmann et al., 2012). China is also an emerging gas producing country with significant potential for shale gas production. For example, in the Sichuan Basin, the Weiyuan-Changning and Fuling marine shale gas fields have reached industrial-scale shale gas production. However, gas-shale plays in China are not only of marine but also of transitional or continental origin (Zou et al., 2010). Examples for such plays are the Palaeozoic shales of the Ordos Basin which are studied here (Fig. 2.1a).

In shales, gas is partly stored as free gas in fractures and pores, partly adsorbed on the surface of OM and clay particles, but also occurs dissolved in kerogen, asphaltenes, residual water and liquid hydrocarbons (Curtis, 2002; Jarvie et al., 2007). It is difficult to distinguish between adsorbed gas and dissolved gas using commonly applied experimental procedures. Hence, the term “sorption” is referred to indicate both adsorbed gas and dissolved gas (Montgomery et al., 2005). The storage capacities of sorbed gas differs in shales, with the sorbed gas accounting for 20%–85% of the total gas (Curtis, 2002). In principle, TOC content, which positively correlates with the increase of micro-porosity in shales, is considered as the main control on methane sorption capacity, since gas is preferentially sorbed in micro-pores due to their great sorption potential and large internal surface areas (e.g. Chalmers and Bustin, 2007; Ross and Bustin, 2007; Gasparik et al., 2014; Yang et al., 2015), whereas the type of OM and its maturity are of less importance (Ross and Bustin, 2009; Zhang et al., 2012). Further, sorption capacity is affected by the content of clay minerals (Ross and Bustin, 2007, 2009; Ji et al., 2012; Liu et al., 2013; Fan et al., 2014), micro-nano pore structure, moisture content (Ross and Bustin, 2007; Merkel et al., 2015, 2016; Yang et al., 2017a; Shabani et al., 2018), pressure and temperature conditions (Gasparik et al., 2012; Zhanget al., 2012; Yang et al., 2015) and effective overburden pressure (Gaus et al., 2021).

In this study, Upper Paleozoic shales from the Quan 14 well, drilled in the Southern Exploration and Development Zone (Fig. 2.1b) were sampled and studied by means of elemental analyses, organic petrography, XRD and petrophysical measurements. The major goal of this study is to characterize porosity and sorption capacity of these shales in the context of kerogen quantity, thermal maturity and mineralogy. The results of this study can be used to assess shale gas potential of these rocks under variable temperature and pressure conditions.

## 2.3 Geological setting

The Ordos Basin is situated in the central part of the North China Plate with an area of  $26 \times 10^4$  km<sup>2</sup> (Fig. 2.1a) and is surrounded by the Yin Mountains, Qinling Mountain, Helan Mountains, Liupan Mountain and Lvliang Mountain (Fig. 2.1c) (Yang et al., 2005). The basin can be divided into six structural units (Fig. 2.1c): the eastern Jinxi Fold Belt, the western Tianhuan Sag and the western Edge Thrust Belt, the southern Weibei Uplift, the northern Yimeng Uplift, and the center Yishan Slope (Yang et al., 2016). The basin is a large asymmetric syncline which includes a narrow, steeply dipping western limb and a broad, gently dipping eastern limb, forming an axis in the Tianhuan Sag. The study area is

located in the southeastern Yishan Slope (Fig. 2.1c). Here, the strata are generally dipping below 1° to the west into the basin (Fig. 2.1d).

The evolution of the basin took place during five tectonic-sedimentary stages: (1) rifting stage in the Middle-Late Proterozoic Era; (2) shallow marine platform stage during the Early Paleozoic Era; (3) littoral plain stage in the Late Paleozoic Era; (4) hinterland basin stage during the Mesozoic Era; and (5) peripheral faulted basin in the Cenozoic Era (Yang et al., 2005).

Generally, the study area was a broad, gentle, and west-dipping monocline during the Late Paleozoic period (Ding et al., 2013). During the deposition of the Carboniferous Benxi Formation, an extensive tidal flat-lagoon environment led to the deposition of basal bauxitic mud-stones interbedded with thin limestones and sandstones (Yang et al., 2005, 2017b; Ding et al., 2013). During the Early Permian, the Shanxi Formation developed with peat deposits, shallow-lacustrine mudstones and minor marine carbonates (Yang et al., 2005; Ding et al., 2013).

## 2.4 Samples

Fig. 2.2. Generalized Paleozoic chrono- and lithostratigraphic chart with corresponding depositional environments of the study area (modified after Ding et al. (2013)).

In order to investigate the effect of lithology on sorption capacity, twelve core samples with great lithologic variation including shales and carbonates from well Quan 14 (Fig. 2.1b) were sampled from the Carboniferous Benxi Formation (3226–3250 m depth) and Permian Shanxi Formation (3160–3176 m depth) (Fig. 2.2).

#### 2.4.1 Benxi Formation

The Benxi Formation is dominated by delta facies as well as restricted platform facies including shelf, lagoon and barrier coast and contains two relatively thin shale layers (cumulative thickness is approximately 30 m) with interbedded thin sandstones in the study area (Ding et al., 2013).

The TOC content of the Benxi Formation ranges between 0.07 and 9.92% (Xiong et al., 2017). The maturity of the Benxi Formation reached over-maturity with vitrinite reflectance ( $VR_r$ ) ranging from 2.44 to 3.12% (Xiong et al., 2017).

The Benxi shales are dominated by clay minerals with mean values of around 67% followed by quartz (mean values are about 22%) and pyrite (Ding et al., 2013; Xiong et al., 2017).

#### 2.4.2 Shanxi Formation

The Shanxi Formation consists of fluvio-deltaic deposits containing two to four sets of grey-black shale with a rather consistent cumulative thickness ranging from 90 to 110 m. These shales are interbedded with thin sandstone, siltstone and coal beds with highly variable TOC contents (Fig. 2.2) (Ding et al., 2013; Yang et al., 2017b).

Throughout the southeastern Yishan Slope, the maturity of the Shanxi Formation is slightly lower than that of the Benxi Formation with  $VR_r$  ranging from 2.3 to 3.1% (Ding et al., 2013; Xiong et al., 2017; Yang et al., 2017b).

In terms of mineralogy, the Shanxi Formation shales are mostly composed of clay minerals (mean values are around 60%), followed by quartz with mean values of about 36%, along with smaller amounts of siderite and pyrite (Ding et al., 2013; Xiong et al., 2017; Yang et al., 2017b). Because of the low TOC contents and the grain size, meso-pores and macro-pores rather than micro-pores contribute to the porosity of the Shanxi Formation shales (Xiong et al., 2017; Yang et al., 2017b). Fluvio-deltaic shales are often characterized by grain sizes between 2 and 20  $\mu\text{m}$ , representing fine-grained siltstones rather than claystones (Scheidt and Littke, 1989; Littke et al., 1997).

### 2.5 Methods

#### 2.5.1 Elemental composition (TOC, TIC and TS)

TOC and inorganic carbon (TIC) contents were measured with a Liqui TOC II analyzer (Elementar Analysen System GmbH, Germany) in one run. About 0.1 g of powder was combusted in an oxygen current in two subsequent heating stages (550 °C for 600 s followed by 1000 °C for 400 s). TOC and TIC contents were assessed by quantifying the amounts of  $\text{CO}_2$  released at 550 °C and 1000 °C during this procedure, respectively.

The total sulfur (TS) content was measured using a Leco S 200 sulfur analyzer (precision is < 5% error, detection limit 0.001%).

### 2.5.2 Organic petrography

VR<sub>r</sub> measurement was performed on a Zeiss Axioplan microscope in non-polarized light at a wavelength of 546 nm using a Zeiss Epiplan-Neofluar oil immersion objective (50×) (refraction index  $n_D = 1.518$  at 23 °C). A mineral standard of known reflectance was used for calibration. Here, the instrument was calibrated with a gadolinium-gallium-garnet (1.72% reflectance) prior to each measurement. Whenever possible, at least 100 vitrinite particles were measured on each sample and the mean random reflectance values were calculated using the DISKUS Fossil software (Technisches Büro Hilgers).

The maceral composition was observed using a Zeiss Axio Imager. M2m microscope and microphotographs were taken with the same instrument. Samples were analyzed in oil immersion with 500× total magnification and Fossil (Hilgers) was used as processing software. Details on preparation of polished samples and microscopic equipment are found in Zieger and Littke (2019).

### 2.5.3 X-ray diffraction (XRD)

Measurements on randomly oriented powders were performed on a Huber MC9300 diffractometer using Co K $\alpha$ -radiation (45 kv, 35 mA). During the analysis, an immobile divergence slit (1.8 mm, 1.45°), a graphite monochromator, and 58 mm and 0.3 mm spacing Soller slits are used to illuminate the sample. The diffracted beam was measured via a scintillation detector with 0.02° 2 $\theta$  step size and 20 s step counting time. A scan rate of 2 $\theta$ /min was used in the testing angle range of 2–76° for recording of diffractograms. Rietveld refinement was used for quantitative phase analysis. BGMN software and customized clay mineral structure models were applied after Ufer et al. (2008).

Powders were prepared by manually grinding sample material in a mortar and milling to a fraction size of less than 200 mesh. After adding 20 wt% of Al<sub>2</sub>O<sub>3</sub> as an internal standard, each sample was put into a McCrone Micronising mill for 20 min to assure uniform crystallite sizes. In order to avoid dissolution of water-soluble components and strain damage, milling was done in ethanol.

### 2.5.4 Porosity and specific pore volume

In this study, porosity ( $\Phi$ ) was determined on irregularly shaped samples by combining grain densities from helium expansion (pycnometry) experiments and bulk densities measured by the buoyancy method (Archimedes method):

$$\Phi = \left(1 - \frac{\rho_b}{\rho_{gr}}\right) \quad (2.1)$$

Here,  $\rho_b$  (kg/m<sup>3</sup>) and  $\rho_{gr}$  (kg/m<sup>3</sup>) are the bulk and grain densities, respectively.

Samples were first cut into irregular shaped blocks with bulk volumes between 5 and 20 cm<sup>3</sup> and dried in a vacuum oven at 105 °C for 24 h to remove moisture and other sorbed fluids. Then, grain densities were measured on a self-customized He-Pycnometer. Details on the experimental set-up, procedure and evaluation are in detail given by Ghanizadeh et al. (2014).

For the buoyancy method, the dry sample weights  $m_d$  (g) were first measured, then the saturated sample mass  $m_w$  (g) was determined after evacuating and saturating them with deionized water for more than oneweek. Finally, the immersed weights  $m_s$  (g) of the saturated samples indeionized water were measured. Based on this,  $\rho_b$  was calculated with:

$$\rho_b = \frac{m_d \cdot \rho_w}{m_s - m_w} \quad (2.2)$$

Here,  $\rho_w$  (0.99 g/cm<sup>3</sup>) is the density of deionized water at laboratory conditions.

Specific pore volume (SPV) which is pore volume normalized to unit sample mass can be expressed as:

$$SPV = \frac{V_p}{m_d} = \frac{1}{\rho_b} - \frac{1}{\rho_{gr}} \quad (2.3)$$

## 2.5.5 High-pressure methane sorption experiments

### 2.5.5.1 High-pressure/temperature manometric sorption setup

A scheme of the manometric setup designed to measure sorption isotherms up to 25 MPa and 120 °C is shown in Fig. 2.3. The used experimental set-ups, calibration, and measuring procedure have been described in detail by Gasparik et al. (2014). The high-pressure/temperature manometric sorption set-up (HPHT) consists of a reference cell (RC) and a sample cell (SC). RC and SC are placed within a low (45 °C) and high-temperature zone (up to 120 °C), respectively, to keep the temperature-sensitive parts offthe high-temperatures. The volumes ofthe RC and SC were calibrated as a function of temperature using tungsten carbide balls with certified volumes.

Fig. 2.3. Schematic diagram of the high-pressure/temperature manometric sorption setup (modified after Gasparik et al. (2014)).

### 2.5.5.2 Methane excess sorption experiments

Methane excess sorption isotherms were measured at 45 °C on 12 powdered samples. Besides, four shale samples were selected from the two formations for experiments at elevated temperatures of 70 °C, 95 °C and 120 °C. Methane of ultra-high purity (99.999%) was used as the sorbate. The procedure consists of the following steps:

1. Drying samples in a vacuum oven at 105 °C for 24 h to remove moisture and other sorbed fluids.
2. Installation of samples in SC.
3. Leak testing (< 5 mbar per hour at 200 bar).

4. Void volume ( $V_v$ ) calibration with helium used as a non-sorbing reference gas by helium expansion.  $V_v(\text{m}^3)$  denotes the void volume in the SC. Then the whole setup was evacuated to remove previous helium via the vacuum pump before starting the methane sorption experiment.

5. Methane sorption experiment after evacuation. In a manometric sorption measurement, the excess sorption  $m_{\text{excess}}$  (also denoted Gibbs surface excess (Sircar, 1999)) is then stepwise calculated from the difference of the total amount of gas transferred into the SC ( $m_{\text{transfer}}$ ) and the storage capacity of  $V_v$  (non-sorption case):

$$m_{\text{excess}} = m_{\text{transfer}} - \rho_g(P, T) \cdot V_v \quad (2.4)$$

$m_{\text{transfer}}$  is a cumulative sum of the volume of the reference cell ( $V_r$ ) multiplied with the gas density difference in the RC before and after expansion into the SC:

$$m_{\text{transfer}} = \sum_{j=1}^n V_r (\rho_{RC}^j - \rho_{RC}^{j+1}) \cdot V_r \quad (2.5)$$

Helium and methane densities were calculated using the GERG equation of state (Kunz and Wagner, 2012). Results are then presented in molar units normalized to sample mass (mmol/g).

#### 2.5.5.3 Blank test

A blank test can be used to reduce unknown errors that depend on each individual device. These errors can originate from systematic errors in the pressure and temperature reading, errors in the equation of state and the calibration (Gasparik et al., 2014). For all setups, blank sorption tests with the measuring gas were performed on non-sorbing tungsten carbide balls at the corresponding temperatures. “Raw” excess sorption isotherms were “blank” corrected by subtracting the “blank” isotherms at an equivalent  $V_v$ . For details, the reader is referred to Gasparik et al. (2014).

#### 2.5.5.4 Parameterisation of excess sorption isotherms

Excess sorption isotherms were fitted with a 3-parameter Langmuir-type model:

$$n_{\text{excess}}(P, T) = n_{\infty} \cdot \frac{P}{P + P_L(T)} \cdot \left(1 - \frac{\rho_g(P, T)}{\rho_a}\right) \quad (2.6)$$

Here  $n_{\text{excess}}$  (mmol/g) corresponds to the excess sorbed amount at a given  $T$  (K) and  $P$  (MPa).  $n_{\infty}$  (mmol/g) represents the Langmuir methane sorption capacity at full occupancy of all sorption sites (infinite pressure) and  $P_L$  (MPa) denotes the Langmuir pressure at which half the sorption capacity is reached.  $\rho_g$  (kg/m<sup>3</sup>) and  $\rho_a$  (kg/m<sup>3</sup>) are the free and sorbed phase densities of methane, respectively.

#### 2.5.5.5 Thermodynamics of methane sorption

For constant absolute sorption, the relationship between required equilibrium  $P$  and sorption  $T$  can be used to calculate its thermodynamic parameters including  $\Delta H$  (molar enthalpy),  $\Delta S$  (molar entropy) and  $Q_{st}$  (isosteric heat) according to equation 2.7.

$$\ln(P_L) = \frac{\Delta H}{R \cdot T} - \frac{\Delta S}{R} + \ln(P^0) = -\frac{Q_{st}}{R \cdot T} - \frac{\Delta S}{R} + \ln(P^0) \quad (2.7)$$

here  $P^0$ , taken as 0.1 MPa, is the pressure at the perfect-gas reference state (Myers and Monson, 2002),  $\Delta H$  ( $-Q_{st}$ ) and  $\Delta S$  are determined from the slope and the y-axis intercept values of regression line on the plot of  $\ln(P)$  versus  $1/T$ , respectively (Zhang et al., 2012).

#### 4.5.6 Calculation of total gas and free gas storage capacity

Gas storage capacity estimates of shale need to consider free and sorbed gas. For high-pressure gas sorption, it is important to realize that the sorbed phase occupies a non-negligible volume. There are two ways of considering the gas stored in the sorbed volume  $V_s$  in gas storage calculations: (1) by subtracting  $V_s$  from the pore volume or (2) by subtracting the gas stored in  $V_s$  (at the free gas pressure) from the absolute sorbed amount (Gasparik et al., 2015). With this, it becomes evident that one has to precisely define free and sorbed gas, which historically leads to some confusion. The main problem in approach (2.1) is in the usage of the absolute sorption  $n_a$ :

$$n_{\text{total}} = n_a + n_{\text{free}} \quad (2.8)$$

Here, the free gas storage capacity  $n_{\text{free}}$  is equal to the bulk methane density multiplied by the pore volume and subtracting it by the volume of the sorbed phase. However, on a molecular scale there is no sharp boundary between the densities of the free and sorbed gas phase because the gas is supercritical (Sakurovs et al., 2008). Moreover, the absolute sorption and the sorbed volume cannot be derived experimentally in high-pressure sorption experiments and need to be estimated using an unknown sorbed phase density (Krooss et al., 2002).

However, the total gas storage capacity can be derived in a simpler way using approach (2.2) based on the Gibbs definition as the sum of the excess sorbed storage capacity and a product of the entire pore volume of the shale with the bulk gas phase density. This is practical as all parameters (SPV and excess sorption capacity) are directly measurable.

$$n_{\text{total}} = n_{\text{pore}} + n_{\text{excess}} = SPV \cdot \rho_g(P, T) + n_{\text{excess}} \quad (2.9)$$

Gas storage capacities can be transformed into various units and the conversions are given in the Appendix.

In this definition, sorption is expressed as the amount of gas that can be stored in excess of the storage capacity of a sample with no sorption. This approach highlights also that it is not possible to distinguish between “free” and “sorbed” gas as in practice as each individual gas molecule can continuously transform from a gaseous “free” into a sorbed state and vice versa.

Gas storage capacity estimates based on dry data are maximum values as partial water saturation decreases both, the excess sorption and pore volume (Gasparik et al., 2014; Bruns et al., 2016; Shabaniet al., 2018). Therefore, the water saturation is a critical control that needs to be assessed independently. Moreover, overburden stress will additionally decrease the excess sorption capacity and pore volume of gas shales (Fink et al., 2018; Gaus et al., 2021).

## 2.6 Results

### 2.6.1 Mineralogy and organic petrology

TOC contents of the Shanxi Formation range from 0.77 to 1.98% and of the Benxi Formation from 0.06 to 2.25% (Table 2.1). TS contents are < 0.25% in the Shanxi Formation and significantly larger with up to 10.6% in the Benxi Formation.

*Table 2.1. Total organic and inorganic carbon (TOC, TIC), total sulphur content (TS), vitrinite reflectance (VR<sub>r</sub>), grain and bulk densities ( $\rho_{gr}$  based on He-pycnometry and  $\rho_b$  based on Archimedes), SPV (specific pore volume), for samples from well Quan 14.*

Fm.	Sample ID	Depth (m)	TOC (%)	TIC (%)	TS (%)	VR <sub>r</sub> (%)	$\rho_{gr}$ (kg/m <sup>3</sup> )	$\rho_b$ (kg/m <sup>3</sup> )	SPV (m <sup>3</sup> /kg)

Fig. 2.4. Microscopic observations of identified macerals in the Shanxi (a-c) and Benxi (d-i) formations. Vitrinite and inertinite particles (a), semifusinite and fusinite (b, c), solid bitumen in intergranular spaces (d), structured inertinite and vitrinite (e, f), solid bitumen in intergranular spaces, and partly replaced by secondary, euhedral pyrite (g), framboidal pyrite aggregates and large isolated euhedral pyrite crystals or as small crystals within fossil structures (e, f, g, h). Vitrinite-like structures (possibly rootlets) with several mm length (i, j).

Samples S-1 to S-4 from the Shanxi Formation are silica-rich argillaceous mudstones with clay contents between 66 and 70% and quartz contents between 29 and 32% whereas samples S-5 and S-6 are silicious-argillaceous mudstones with significantly lower clay content around 43%, higher quartz content and a significant fraction of carbonates (Table 2.2). For all Shanxi shales, illite/smectite (I/S) mixed layer is the dominant clay mineral phase.

The Benxi shales can be subdivided into a silica-rich argillaceous (B-1, B-2, B-3, B-6) and carbonate dominated lithotype (B-4, B-5; carbonate content > 94%). Compared to the Shanxi Formation, the silica-rich argillaceous shales have even higher clay (70–80%) and smaller quartz contents (1–15%). Moreover, clay mineralogy significantly differs compared to the Shanxi shales with increased kaolinite content between 35 and 57% (Table 2.2).

Fig. 2.5. Ternary diagram illustrating the normalized mineralogical composition for the samples from the Shanxi Formation and Benxi Formation in the Ordos Basin. Mineralogy is normalized to quartz + feldspar, clays (kaolinite, mixed layer illite-smectite, and chlorite) and carbonates (calcite, dolomite and siderite).

VR<sub>r</sub> of the shales from the Shanxi Formation varies between 2.35 and 2.51% among the samples with an average value of 2.43%. With values ranging from 2.41 to 2.97% (mean = 2.64%) in the Benxi Formation, variance among samples is higher (Table 2.1). OM in shales from the Shanxi Formation is characterized by abundant vitrinite and inertinite particles, and even coal fragments (Fig. 2.4a). Structured inertinite such as semifusinite and fusinite (Fig. 2.4b and c) is common. Pyrite is less abundant as compared to the Benxi Formation samples, which is also supported by the XRD data (Table 2.2, Fig. 2.5). Pyrite is most often represented by small euhedral crystals. Solid bitumen can also be observed in intergranular spaces (Fig. 2.4d). Besides structured inertinite and vitrinite (Fig. 2.4e and f), the Benxi shales show solid bitumen in intergranular spaces, in some cases partly replaced by secondary, euhedral pyrite (Fig. 2.4g). The in some cases high TS values (Table 2.1) are mirrored by the presence of either framboidal pyrite aggregates and large isolated euhedral pyrite crystals or as small crystals within fossil structures (Fig. 2.4e, f, g and h). Sample B-6 shows several mm long vitrinite-like structures that presumably represent rootlets (Fig. 2.4i and j).

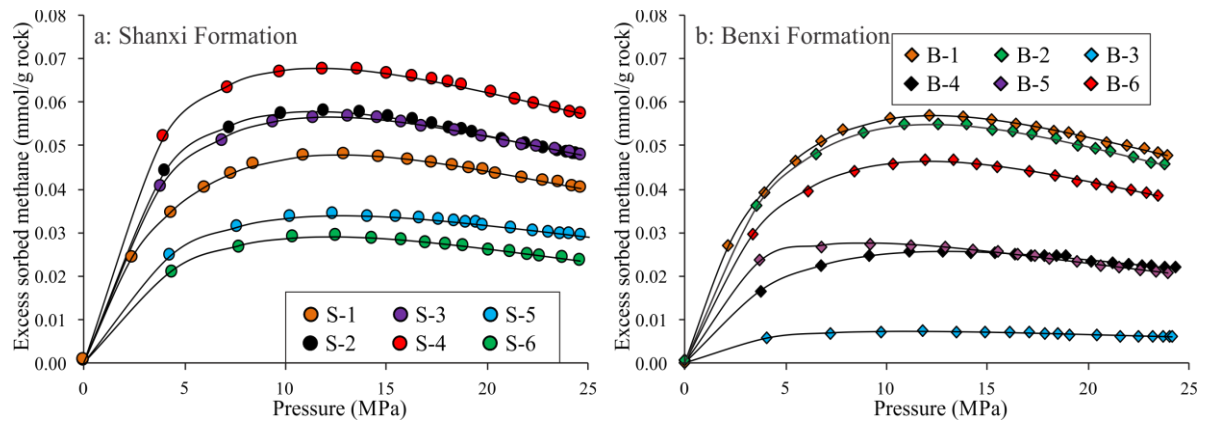

## 2.6.2 Porosity and SPV

The  $\rho_{gr}$  and  $\rho_b$  values as well as porosities of the samples are listed in Table 2.1. The porosity of the Shanxi Formation samples ranges from 4.1 to 7.1%, and of the Benxi Formation samples from 0.5 to 7.7% (Table 2.3). The  $\rho_{gr}$  ranges from 2689 to 2777 kg/m<sup>3</sup> for the Shanxi Formation and between 2694 and 2784 kg/m<sup>3</sup> for the Benxi Formation. The SPV values of the Shanxi Formation are between  $1.51 \cdot 10^{-5}$  and  $2.79 \cdot 10^{-5}$  m<sup>3</sup>/kg, and of the Benxi Formation between  $1.87 \cdot 10^{-6}$  and  $3.00 \cdot 10^{-5}$  m<sup>3</sup>/kg.

## 2.6.3 High-pressure excess methane sorption isotherms

*Fig. 2.6. Methane excess sorption isotherms at 45 °C for samples from the Shanxi (a) and Benxi (b) formation.*

High-pressure excess methane sorption isotherms (45 °C) (Fig. 2.6) illustrate a large variety of sorption capacities with a maximum mostly at approximately 10 MPa.

Sorption parameters fitted with the 3-parameter Langmuir-type model are listed in Table 2.3. For the samples from the Shanxi Formation, the fitted values of  $n_{\infty}$  for the isotherms at 45 °C range from 0.06 to 0.12 mmol/g rock (Table 2.3); fitted  $\rho_a$  values are in the range of 320–393 kg/m<sup>3</sup>; fitted Langmuir

pressures values range from 4.5 to 7.8 MPa; and the maximum  $n_{\text{excess}}$  values vary from 0.029 to 0.068 mmol/g rock. For the samples from Benxi Formation, the fitted  $n_{\infty}$  values for the isotherms at 45 °C range from 0.01 to 0.12 mmol/g rock (Table 2.3); the fitted  $\rho_a$  values are in the range of 321–371 kg/m<sup>3</sup>, quite consistent with the values of the Shanxi Formation; the fitted Langmuir pressure values vary from 2.7 to 8.4 MPa; and the maximum  $n_{\text{excess}}$  values vary between 0.007 and 0.057 mmol/g rock.

Fig. 2.7. Excess sorption isotherms for selected samples from the Shanxi and Benxi formations of the southeastern Ordos Basin measured at temperatures from 45 to 120 °C.

From the 12 samples measured at 45 °C four end-member samples with the highest and lowest sorption capacities were selected for the high temperature measurements. The maxima of the excess isotherms of He samples show the typically decreasing trend of excess sorption capacity and increasing trend of pronounced maxima pressure with increasing temperature (Fig. 2.7). The pronounced excess sorption maxima occur at pressures between 9.68 and 12.89 MPa at 45 °C and increase to values between 21.57 and 24.91 MPa at 120 °C. Here, the excess sorption maxima at these pressures decreased between 0.002 mmol/g (B-3) and 0.017 mmol/g (S-4) (Table 2.4).

Langmuir parameters for the selected samples are shown in Table 2.4. All parameters were obtained for one sample by simultaneously fitting the 3-parameter Langmuir-based excess sorption function to all four isotherms measured at different temperatures (Gasparik et al., 2015).

Table 2.4. Results from high-pressure methane sorption measurements at 45 to 120 °C on four selected samples.  $\Delta H$  and  $\Delta S$  are molar enthalpy and entropy, respectively.

## 2.7 Discussion

### 2.7.1 Thermal maturity and depositional conditions

At high levels of sedimentary diagenesis,  $VR_r$  is probably the best and most widely used parameter for thermal maturity, because most organic geochemical parameters cannot be applied.  $VR_r$  values measured on our sample set are similar to those reported before on both the Shanxi and Benxi formations, which have reached the dry gas petroleum generation stage. TOC values are variable, but partly smaller than reported before (Yang et al., 2016, 2017b; Xiong et al., 2017), which might be related to the location of well Quan 14 at a marginal position on the southeastern Yishan slope.

Both in terms of lithology and mineral content, rocks show strong variability, related to variable depositional settings. This fact is also reflected by highly variable TS contents. In paralic environments, freshwater with little sulfate predominates, but from time to time, transgressive intrusion of seawater provides a massive source of sulfur, while abundant metal ions (in particular iron) and terrestrial OM can be provided by the terrestrial environment, leading to precipitation of iron sulfides as soon as reducing conditions are established in the pore water. Generally, the stronger the intrusion of seawater, the higher the TS content in shales. The processes and depth ranges of microbial sulfate reduction as well as its influence on OM quality have been described in Berner (1984) and Lückge et al. (1999) in great detail. The ratio of TOC to TS can be used to distinguish marine mudstones ( $0.5 < \text{TOC/TS} < 5$ ) and non-marine water-bottom environments ( $\text{TOC/TS} > 10$ ) (Berner, 1984). The values of TOC/TS of

the samples studied cover a wide range and indicate the shift from marine to terrigenous environments as well (Fig. 2.8).

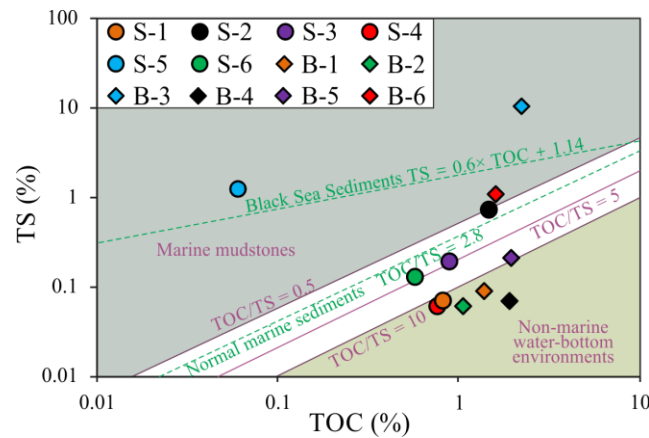

Fig. 2.8. Total sulfur (TS) vs. total organic carbon (TOC) indicating environments of deposition of the Shanxi and Benxi formations of the southeastern Ordos Basin, China.

The observation of abundant vitrinite and inertinite particles, and even coal fragments and roots (Fig. 2.4a, e and f), indicates the terrestrial origin of most OM. This material certainly represents a former type III kerogen, now strongly converted towards carbon-rich residues, which is consistent with conclusions from previous studies (Yang et al., 2016, 2017b; Xiong et al., 2017).

While most samples have a high content of clay minerals, samples B-3 and B-4 show high contents of carbonate. These samples also have low TOC/TS ratios indicating a marine depositional environment. For our sample set, strong marine influence is indicated for Benxi Formation (in agreement with e.g. Ding et al. (2013) and Xiong et al.(2013)) see also Fig. 2.2), but not for Shanxi Formation where the studied samples do not show any marine influence. Clay minerals are clearly dominated by I/S mixed layer in Shanxi Formation, while Benxi Formation shales are characterized by a mixture of both I/S mixed layer and kaolinite. This non-uniform distribution of clay minerals is consistent with previously published data (Ding et al., 2013; Yang et al., 2016, 2017b; Xiong et al., 2017).

## 2.7.2 Mineralogical controls on porosity and methane sorption capacity

For the Shanxi and Benxi shales there is no relationship between TOC content and porosity (Fig. 2.9a). OM is usually not the controlling factor of porosity when TOC content is less than 2.0% (Ghanizadeh et al., 2015; Chukwuma et al., 2018; Fink et al., 2018). In theory, the evolution of porosity with maturity in OM-rich shales follows a non-linear, trough-shaped path that is primarily controlled by compaction, hydrocarbon generation and development of organic porosity during secondary cracking in the over-mature stage (Mastalerz et al., 2013). For Benxi and Shanxi shales, porosity and the total clays for the studied samples show a good correlation indicating that most of the pores reside within the clay fraction (Fig. 2.9a) (see also Yang et al., 2016; Xiong et al., 2017; Yang et al., 2017b).

Fig. 2.9. Total organic carbon (TOC) and total clays as a function of porosity (a) and as a function of Langmuir sorption capacity (b).

For many organic-rich shale lithologies, Langmuir sorption capacity is controlled by TOC content due to its high micro-porosity that provides abundant surface area and sorption sides (Chalmers and Bustin, 2008). In our dataset, there is no relationship between TOC content and Langmuir sorption capacity (Fig. 2.9b). This suggests that TOC content is not the main factor controlling Langmuir sorption capacity of Benxi and Shanxi shales where the overall TOC content is low. Clay minerals can possess comparatively large Langmuir sorption capacities with a rough order of smectite > I/S mixed layer  $\geq$  kaolinite > chlorite  $\geq$  illite (Table 2.5, Ji et al., 2012; Liu et al., 2013; Fan et al., 2014). Smectite content in over-mature gas shales is usually negligible as it is converted to illite and I/S mixed layer with increasing temperatures during diagenesis at depths exceeding 1600–2600 m (Chen et al., 2009) and temperatures exceeding 60–120 °C (Lindgren et al., 1991; Strixrude and Peacor, 2002; Peltonen et al., 2009). Both I/S mixed layer and kaolinite are abundant in Benxi and Shanxi shales, and sorption capacity is positively related to clay content (Fig. 2.9b).

To assess the contribution of clays (I/S mixed layer, kaolinite) and organics to sorption capacity/porosity a linear combination approach was used to predict the Langmuir sorption capacity/SPV of each individual mineral constituent. The Langmuir sorption capacity/SPV is expressed as the sum of the individual components on a mass-fraction base (Yang et al., 2015):

$$n_{\infty} = \sum_{i=1}^n n_i w_i \quad (i = 1, 2, 3, \dots, n) \quad (2.10)$$

$$\Phi = \sum_{i=1}^n \rho_{bulk} SPV_i w_i \quad (i = 1, 2, 3, \dots, n) \quad (2.11)$$

Here  $w_i$  is the mass fraction,  $n_i$  the Langmuir sorption capacity and the product of both the Langmuir sorption capacity of the sample. The calculation of porosity can only be performed on a mass basis of the individual component as the volume fractions are unknown. Therefore, we use the specific pore volume of each individual component ( $SPV_i$ ). With this, similar to sorption the contribution of an individual fraction to porosity can be obtained by multiplying the contribution of the SPV with the samples bulk density.

Table 2.5. Value of Langmuir sorption capacity of individual clay minerals and isolated kerogen.

Variable	Value (mmol/g)	References
Type I kerogen	1.140	Zhang et al. (2012)
Type II kerogen	1.210	
Type III kerogen	1.400	
Smectite	0.380	Ji et al. (2012)
	0.268	Liu et al. (2013)
	0.179	Fan et al. (2014)
I-S mixed layer	0.182	Ji et al. (2012)
	0.138	Fan et al. (2014)
Kaolinite	0.120	Ji et al. (2012)
	0.173	Liu et al. (2013)
	0.155	Fan et al. (2014)
Illite	0.080	Ji et al. (2012)
	0.099	Liu et al. (2013)
	0.154	Fan et al. (2014)
Chlorite	0.100	Ji et al. (2012)
	0.039	Fan et al. (2014)

Considering for Benxi and Shanxi shales that TOC, I/S mixed layer and kaolinite are the main contributors, the following equations are obtained:

$$n_{\infty} = n_{TOC} \cdot w_{TOC} + n_{I/S} \cdot w_{I/S} + n_{Kaolinite} \cdot w_{Kaolinite} + 0 \cdot w_{Framework} \quad (2.12)$$

$$\Phi = \rho_{bulk} \cdot (w_{TOC} \cdot SPV_{TOC} + w_{I/S} \cdot SPV_{I/S} + w_{Kaolinite} \cdot \bar{S}_{Kaolinite} + 0 \cdot w_{Framework}) \quad (2.13)$$

Here  $w_{OM}$ ,  $w_{I/S}$ , and  $w_{Kaolinite}$  are the mass fractions of OM, I/S mixed layer, and kaolinite, respectively,  $n_{TOC}$ ,  $n_{I/S}$ , and  $n_{Kaolinite}$  (mmol/g) are the sorption capacity of OM, I/S mixed layer, and kaolinite, respectively, and  $SPV_{TOC}$ ,  $SPV_{I/S}$ , and  $SPV_{Kaolinite}$  (cm<sup>3</sup>/g) are the SPV of OM, I/S mixed layer, and kaolinite, respectively.

We use linear regression analysis to minimize the Langmuir sorption capacity/porosity of the calculated values with the measured values simultaneously for the whole sample set. With this, the Langmuir sorption capacity/SPV of each component can be determined by using them as a fitting factor. The approach is able to match the measured data reasonably well (Fig. 2.10a and b). The resulting SPV is 0.081 cm<sup>3</sup>/g for TOC, 0.036 cm<sup>3</sup>/g for I/S mixed layer and 0.026 cm<sup>3</sup>/g for kaolinite. Except for the carbonates (B-3 and B-4), which have almost no porosity, porosity is controlled by the clay minerals where more than 90% of the pore volume occurs (Fig. 2.10c). This shows that OM, in contrast to other shale systems, has a negligible effect on the volumetric gas storage in Benxi and Shanxi shales.

Fig. 2.10. Fitted porosity (a) and Langmuir sorption capacity (b) values ( $n_{\infty}$ ) using a linear combination approach vs. measured values, and the overall contribution of individual components (c and d).

Similarly, the obtained Langmuir sorption capacities match the measured values reasonably well and we obtained 1.20 mmol/g for TOC, 0.14 mmol/g for I/S mixed layer and 0.10 mmol/g for kaolinite. Our Langmuir sorption capacities of TOC are close to the sorption capacity of isolated kerogen (between 1.14 and 1.4 mmol/g) measured by Zhang et al. (2012). For the clay minerals, they are in good agreement with results from measurements on pure clay minerals (Illite and I/S mixed layer between 0.08 and 0.18 mmol/g, kaolinite between 0.12 and 0.17 mmol/g) (Table 2.5). Sorptive storage in Benxi and Shanxishales mostly occurs in the clay fraction with 80–99% of the overall sorption capacity (excluding the carbonates). In all clay-rich shales, organics contribute very little with less than 20% (Fig. 2.10d).

Compared to other over-mature ( $VR_r > 1.3\%$ ) shale formations Benxi and Shanxi shales possess comparatively low sorption capacities ( $< 0.13$  mmol/g) due to their low TOC content (Fig. 2.11a). Although the high clay content increases the sorption capacity in comparison to other organic-lean shales ( $< 2.5\%$  TOC), organic-rich shales possess significantly larger sorption capacities resulting in an overall positive trend between TOC content and Langmuir sorption capacity.

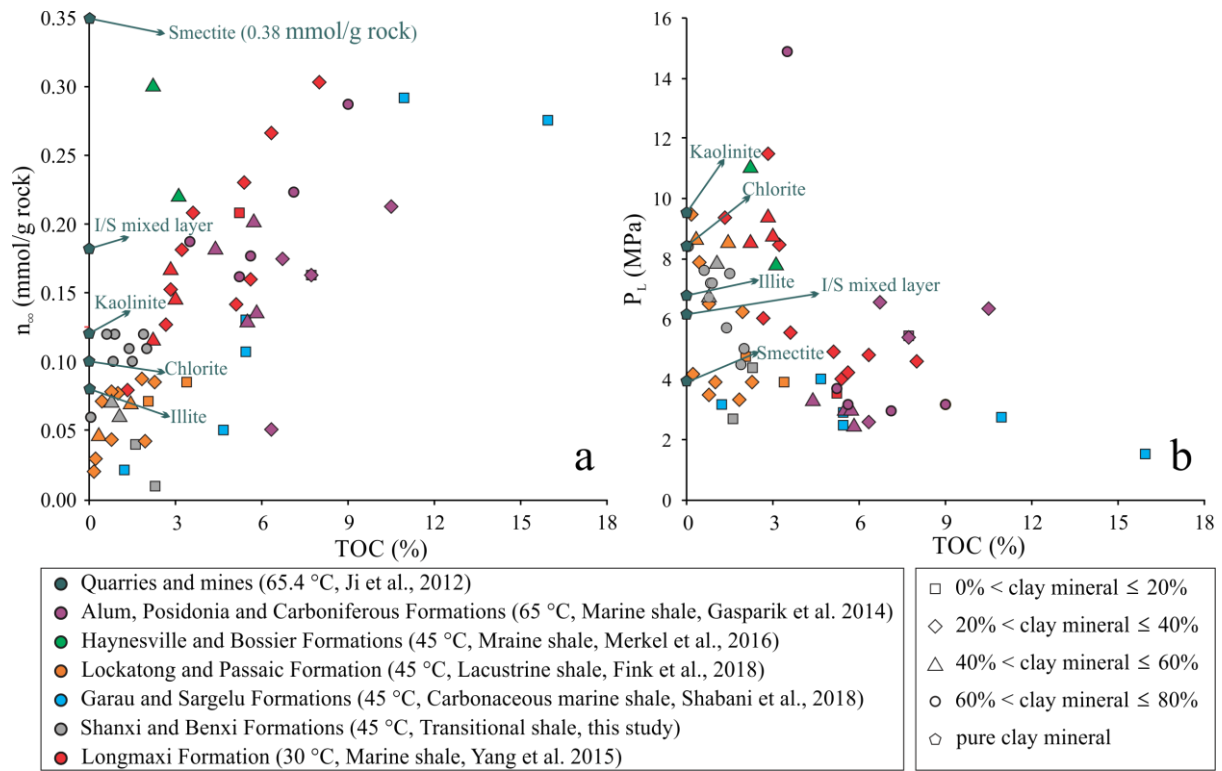

Fig. 2.11. Comparison of sorption capacity (a) and Langmuir pressure (b) of Benxi and Shanxi shales with over-mature ( $VR_r > 1.3\%$ ) lacustrine and marine shales. All data was measured at dry condition between 30 °C and 65.4 °C.

Langmuir pressures of overmature shales range mostly between 2 and 10 MPa at laboratory conditions (dry condition, 30 °C–65.4 °C) (Fig. 2.11b). The scatter in  $P_L$  values is very large below 4% TOC and significantly decreases with increasing TOC. The reason is presumably that at low TOC contents the  $P_L$  values result from sorption on strongly varying mixtures of clay minerals and organics. Here, samples with relatively high organic and low clay mineral content have tentatively lower  $P_L$  values and vice versa (Fig. 2.11b) as the  $P_L$  values of pure clays are significantly larger compared to pure organics.

### 2.7.3 Effect of temperature

Thermodynamic parameters describing the sorption process can be obtained by analyzing the temperature dependence of the  $P_L$  based one equation (7) (Fig. 2.12). Sorption entropy  $\Delta S$  varies from -14.12 to -24.69 kJ/mol and isosteric heat  $\Delta H$  from -80.74 to -104.22 J/mol/K (Table 2.4). A linear relationship exists between the  $\Delta H$  and  $\Delta S$  (Fig. 2.13) which is caused by the nature of physical (Van-der-Waals) bonding of the gas and the solid (Gasparik et al., 2013). Compared to previously published data on pure clays and kerogen (Ji et al., 2012; Zhang et al., 2012; Rexer et al., 2014), Benxi and Shanxi shales plot between type III kerogen and I/S mixed layer. The thermodynamic parameters closely resemble the mineralogy of the samples. Samples where sorption is dominated by I/S mixed layer and kaolinite plot close to the pure clays whereas samples with little clay mineral content show thermodynamic properties of kerogen type II and III (Fig. 2.13).

Fig. 2.12. Determination of sorption enthalpy and entropy of the selected shale samples from the Shanxi and Benxi Formations.

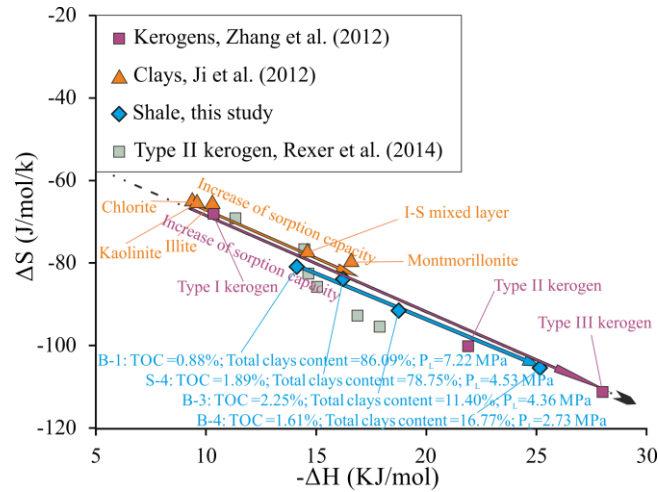

Fig. 2.13. Plot of isosteric heat vs. molar entropy for the selected samples from the Shanxi and Benxi formations of the southeastern Ordos Basin and for the pure clay minerals as well as kerogens.

## 2.7.4 Gas storage capacity

### 2.7.4.1 Depth-dependence of gas storage capacity

Sorption capacity, free gas storage capacity and total gas storage capacity at a certain depth can be estimated by equation (9). Here, it is considered that the shales are dry (0% water saturation), the formation is over consolidated and uplifted to the current depth with no changes in porosity. Moreover, we use a surface temperature of 15 °C and a geo-thermal gradient of 2.8 °C/100 m based on data from Yu et al. (2017).

Gas storage capacity increases with depth up to 0.32 mmol/g for sample S-4, which possesses the largest storage capacity among the Benxi and Shanxi samples (Fig. 2.14). At shallow depths, the excess sorbed gas storage generally dominates the total storage capacity of Benxi and Shanxi shales, whereas

the free storage capacity become sincreasingly important with depth. For all samples, the excess sorbed gas storage capacity decreases after it reaches its maximum value ( $< 1000\text{m}$ ), and the corresponding depth of the maximum of the sorbedgas storage capacity is positively related to the  $P_L$  value.

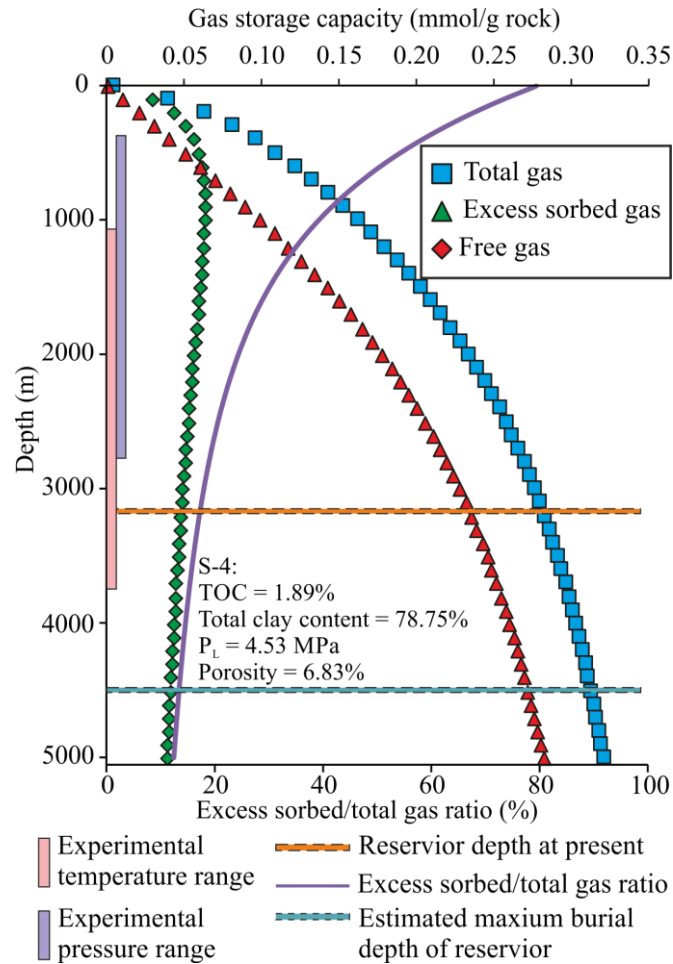

Fig. 2.14. Excess sorbed, free and total gas storage capacity and excess sorbed/total gas ratio as a function of depth. Depth trends are exemplarily shown on the basis of the sample possessing the largest sorption capacity (S-4).

Maximum burial of the Shanxi and Benxi shales in the study area occurred in the Middle Cretaceous (Yu et al., 2017) where they were buried to a depth of up to 5000 m and experienced temperatures up to 140 °C. Gas generation ceased in the Late Cretaceous (100 My) after uplift to 2900 m. The formation subsided again to 3200 m after the Middle Pliocene to the present depth (Ding et al., 2013; Yu et al., 2017).

At current reservoir conditions (Pore pressure = 30 MPa,  $T = 100\text{ °C}$ ) more than 80% of the gas is estimated to be stored as free gas whereas only 20% is stored as excess sorbed gas. Therefore, sorptive gas storage for such deep reservoirs is of minor importance. Further considering that already small amounts of reservoir water considerably decrease the sorption capacity of shales by competitive sorption, sorbedgas storage capacity for Benxi and Shanxi shales may even be in the range of the uncertainty of free gas storage estimates (Merkel et al., 2015, 2016; Shabani et al., 2018).

#### 2.7.4.2 Changes in free and excess sorbed gas during production from the shale matrix

During the production of a shale gas reservoir the pressure in the shale matrix, where most of the shale gas is stored, is gradually reduced. This leads to changes in the ratio between “free” and “excess sorbed” gas in the nano-pores. As physisorption is a fast and reversible process, it is not possible to differentiate between individual “sorbed” and “free” methane molecules and an equilibrium between the sorbed and free phase upon changes in the P-T conditions will occur almost instantaneously. Using the reservoir conditions ( $P = 30$  MPa and  $T = 373.15$  K), the gas production and changes in “free” and “excess sorbed” gas can be calculated (Fig. 2.15). During depletion of a given matrix block, the “excess sorbed” gas content changes almost insignificantly until a pressure of around 10 MPa below which the “excess sorbed” gas content will be reduced. Therefore, sorption does not add any significant benefit in shale gas production at high pressure. Fig. 2.15 illustrates that the increase of produced gas amount is negligible at high pressure where some of the free gas even translates into “excess sorbed” gas during the early time of gas production. Only when the pore pressure in the matrix is reduced significantly, below roughly 10 MPa will “excess sorbed” gas contribute to production. Additionally, a matrix block with high excess sorption compared to a sample with no sorption (only free gas) will release less gas at high pressure due to the transfer of “free” into the “excess sorbed” phase (maximum in the excess sorption isotherms). Thus, it is very important to forecast the reduction of gas pressure in each part of the matrix to judge the relevance of sorption during production. However, depending on the production behavior of a given reservoirs pore pressures may be too high within the matrix and release of “excess sorbed” gas does not significantly add to overall production.

Fig. 2.15. Cumulative gas production from a matrix block of a reservoir at 3000 m depth and 100 °C upon depletion. During production at high pressures ( $>12$  MPa) the change in “excess sorbed” gas content is negative and only the free gas content changes (a). The ratio of the current change of “excess sorbed” gas to the total gas is negative at pressures above the maximum in the excess sorption isotherm (20 MPa). Upon pore pressure reduction below these values will “excess sorbed” gas start contributing to total gas production. The curves were calculated based on the experimental results of sample S-4 (b).

## 2.8 Conclusions

1) Porosity and excess sorption capacity of over-mature Shanxi and Benxi shales are controlled by their high clay mineral content (up to 80%). In contrast to other shales, TOC due to its low content (< 2.3%), has a negligible effect on gas storage properties.

2) Excess sorptive storage generally dominates the storage capacity of Benxi and Shanxi reservoirs at shallow depths whereas the volumetric “free” gas storage prevails in deeper reservoirs.

3) Methane sorption does not have a positive effect on gas production at high pressure. Only when the pore pressure in the matrix is reduced significantly will “excess sorbed” gas contribute to production. This has major implications for deep reservoirs where pore pressures in the matrix may not be sufficiently reduced before production ceases.

4) Both Benxi and Shanxi shales are characterized by comparatively low porosities, sorption capacities and gas storage capacities compared to producing marine shale gas systems. Combined with the large amount of clay minerals that make hydraulic fracturing more difficult they are regarded unfavourable for shale gas exploitation.

### Conversion formula

$$n_{\text{sorbed}} \left( \frac{\text{mol (CH}_4\text{)}}{\text{m}^3 \text{ (rock)}} \right) = n_{\text{excess}} (\text{mmol/g}) \cdot \rho_b (\text{kg/m}^3) \quad (2.12)$$

$$n_{\text{total}} \left( \frac{\text{mol}}{\text{m}^3 \text{ (rock)}} \right) = \left[ \frac{\text{SPV (m}^3/\text{kg)} \cdot \rho_g (\text{kg/m}^3)}{M_{\text{CH}_4} (\text{kg/mol)}} + n_{\text{excess}} (\text{mmol/g}) \right] \cdot \rho_b (\text{kg/m}^3) \quad (2.12)$$

Here  $n_{\text{sorbed}}$  and  $n_{\text{total}}$  corresponds to the sorbed and total gas storage capacities, respectively.  $n_{\text{excess}}$  (mmol/g) corresponds to the excess amount sorbed at T (K) and P (MPa).  $\rho_b$  (kg/m<sup>3</sup>) is the bulk densities.  $\rho_g$  (kg/m<sup>3</sup>) is the free phase densities of methane. SPV (Specific pore volume) is pore volume normalized to unit sample mass.  $M_{\text{CH}_4}$  is the molality of methane.

### **3 Paleo-depositional environment, origin and characteristics of organic matter of the Triassic Chang 7 Member of the Yanchang Formation throughout the mid-western part of the Ordos Basin, China**

#### **3.1 Abstract**

A comprehensive geochemical and petrographic study was performed on 23 clay-rich shale samples collected from 18 wells drilled in the mid-western part of the Ordos Basin to investigate the characteristics and thermal maturity of organic matter as well as the paleo-depositional environment of the Chang 7 Member within the Triassic Yanchang Formation. The samples are characterized by moderate to very high organic carbon (TOC) contents ranging from 0.24% to more than 24.83% (2.72% on average) and total sulfur (TS) contents of 0.06% to 6.51%. Rock-Eval  $S_1$  and  $S_2$  values range from 0.13 to 3.70 mg HC/g rock and 0.62 to 92.50 mg HC/g rock, respectively, implying good to very good hydrocarbon generation potential for most of the samples. Rock-Eval data and petrographical observations reveal that the kerogen is mainly composed of type II to type III, consisting of a mixture of aquatic and terrigenous organic matter. The aliphatic fractions show variable monomodal to bimodal distributions of normal alkanes. Different parameters such as TOC/TS and molecular biomarker data imply that the Chang 7 member is a typical clay-rich source rock deposited in a sulphate-poor lacustrine to fluvio-deltaic environment under oxic to sub-oxic conditions with substantial input of organic matter derived from higher land plants, mainly conifers. Low values of gammacerane further indicate a low salinity of the paleo-lake. Average  $T_{max}$  values of 445 °C, vitrinite reflectance values between 0.68% and 0.88%, biomarker parameters, such as sterane ratios of  $C_{29}$   $\alpha\alpha\alpha$  20S/(20S + 20R) and  $C_{29}$   $\beta\beta$ /( $\beta\beta$  +  $\alpha\alpha$ ), and maturity indices based on aromatic compounds, indicate a thermal maturity within the oil window for the studied samples, showing some regional variability within the mid-western Ordos Basin.

#### **3.2 Introduction**

Source rocks are increasingly being regarded as hosts for commercial unconventional hydrocarbons reservoirs, i.e. gas- and oil-shale reservoirs. One prominent example for such a resource is the lacustrine Chang 7 Member in the Ordos Basin, China. Compared to marine settings, lacustrine environments are more complex regarding their deposetting and are prone to be affected by terrestrial material. On the one hand, the depositional facies, depositional environment and organic matter (OM) composition are more diverse and are easy to be disturbed by terrestrial input due to the small scale of lake systems as compared to marine settings. On the other hand, seasonal/periodic paleo-climates can trigger changes in water chemistry and salinity in lake systems over short periods of time, whereas salinity and water chemistry are quite persistent in marine settings. In fact, the paleo-depositional environment exerts a major control on the abundance and quality of OM preserved in sediments, making it an important factor in quantifying the hydrocarbon potential of source rocks on a basin scale (Jones

and Manning, 1994). In turn, thermal maturity of a source rock plays a critical role in the transformation of OM into mobile hydrocarbons.

Fig. 3.1. Schematic map showing (a) the Ordos Basin with facies boundaries of the Upper Triassic (after Qiao et al., 2020 and Chen et al., 2017), (b) the study area and well locations (note the different symbols depending on well location, e.g. north, west), and (c) a cross section from west to east of the central Ordos Basin (see a) for position; after Hanson et al. (2007).

The Ordos Basin is the second largest sedimentary basin in China (Li et al., 2016), and has a long depositional history from the Lower Paleozoic to Mesozoic and Cenozoic. It developed on Precambrian metamorphic basement. Following the dry climate of the Permian, plants began to flourish again in the Late-Middle Triassic in the region of the today's Ordos Basin and the most important source rocks of the basin were deposited during the Late Triassic. Triassic hydrocarbon deposits were first discovered

in the 1980ies with the Triassic Chang 7 Member of the Yanchang Formation being regarded as the most important source rock for these accumulations (Hanson et al., 2007; Duan et al., 2008). Although there have been numerous publications on the Chang 7 Member (e.g., Yang et al., 2008; Zhang et al., 2017; Xu et al., 2019; Chen et al., 2019a, Chen et al., 2019b), there is still a lack of detailed information on organic geochemical parameters. Further, there are some controversies related to the depositional environment prevailing during the deposition of the Chang 7 Member which need to be clarified. For example, there are significant differences between the reported geochemical characteristics e.g., with respect to the isoprenoids/*n*-alkane ratios, terpanes and gammacerane (Gam) indices and sterane data (Duan et al., 2008; Li et al., 2017; Pan et al., 2017; Xu et al., 2019). As a result, there are different interpretations of depositional environment, type of kerogen, redox conditions as well as salinity of the paleo-lake. These differences might be caused by the extensive regional distribution of the Chang 7 member and thus heterogeneity of rock properties indicating the necessity of systematic regional studies. The area selected for the study presented here is located in the major hydrocarbon exploitation area in the mid-western Yishan Slope (Fig. 3.1a). The area is characterized by a low level of tectonic deformation, i.e. there is little faulting and folding (Yang, 2002).

The goal of this study is to apply organic petrography, carbon and sulfur contents, Rock-Eval pyrolysis and molecular organic geochemistry on aliphatic and aromatic hydrocarbons in order to i) reconstruct the depositional environments prevailing during deposition of the Chang 7 member and gain information on the biological precursors of its OM and ii) to quantify thermal maturity in the mid-western part of the Ordos Basin (Fig. 3.1b), for which almost no such information has been published so far. Besides, this study contributes to the understanding of OM-rich Late Triassic rocks, which are less widespread and have been less studied than those of Carboniferous, Jurassic, Cretaceous, and Cenozoic times.

### 3.3 Geological setting

The Ordos Basin, a sedimentary basin with a complex, long-lasting subsidence, several phases of uplift and erosion interrupting polycyclic sedimentary deposition, is situated in the central part of the North China Plate covering an area of  $26 \times 10^4 \text{ km}^2$  where it developed on an Archean–Early Proterozoic rigid crystalline basement (Yang et al., 2005). It is surrounded by the Yin Mountain to the north, the Qinling Mountain to the south, the Helan Mountains to the northwest, the Liupan Mountain to the southwest, and the Lvliang Mountain to the east (Fig. 3.1a). The basin is divided into six structural units based on the geological evolution history and the characteristics of the Mesozoic geological structures; the eastern Jinxi Fold Belt, the western Tianhuan Sag and the Western Edge Thrust belt, the southern Weibei Uplift, the northern Yimeng Uplift, and the central Yishan Slope (Fig. 3.1a). The evolution of the basin took place during five tectonic-sedimentary stages: (1) the aulacogen stage in the Middle-Late Proterozoic; (2) the shallow marine platform stage during the Early Paleozoic; (3) the

littoral plain stage in the Late Paleozoic; (4) the hinterland basin stage during the Mesozoic; and (5) the peripheral faulted basin stage in the Cenozoic (Yang et al., 2005). Corresponding sedimentary rocks include shallow-marine clastic-carbonate deposits, epicontinental sea carbonate platform deposits, coastal carbonate-continental clastic platform deposits, and intra-continental lacustrine-fluvial deposits (Meso- and Cenozoic). During the Late Triassic, the tectonic evolution of the basin was controlled by Indosinian Plate movements which resulted in a persistent regression and the development of an inland basin (Yang et al., 2005).

Fig. 3.2. Simplified stratigraphy of the Ordos Basin and the Upper Triassic Yanchang Formation lithologies and their corresponding depositional environment (modified after Zhao et al., 2015).

The Ordos Basin is considered as a Mesozoic and Cenozoic freshwater continental sedimentary system. The stratigraphic sequence comprises of Middle-Upper Triassic to Quaternary strata wherein the Mesozoic strata constitute the majority of the sediments (Figs. 1c and 2). This sequence overlies a crystalline basement of Archean and Lower Proterozoic age (Watson et al., 1987). The whole basin was

filled with lacustrine and fluvial sediments during the Triassic period, but only the lacustrine deposits are considered to possess hydrocarbon generation potential (Zhang et al., 2015). The Yanchang Formation, which is sub-divided into ten members (Chang 1 to Chang 10), underlies the Jurassic Fuxian Formation and overlies the Middle Triassic Zhifang Formation (Fig. 3.2). The Yanchang Formation first experienced a lacustrine transgression leading to deepening of the water column (Chang 9-Chang 7 periods), followed by successive shallowing of the paleo-lake (Chang 6- Chang 1 periods; Fig. 3.2). The Chang 7 Member was deposited at the deepest and most expansive stage of the Triassic Yanchang Ordos Lake. The thickness of this member varies between 60 and 120 m with the cumulative thickness of the source rocks ranging from 15 to 100 m (Li et al., 2020); it is regarded as an important marker bed in the Yanchang Formation corresponding to the Maximum Flooding Surface (MFS). Lithologically, it is composed of mudstone, siltstone and sandstone (Fig. 3.2). OM-rich successions were deposited in the shallow to deep lake water environments and are restricted to the lower 10 to 40 m of the Chang 7 member in an area of more than  $50 \times 10^3 \text{ km}^2$  (Chen et al., 2017, Fig. 3.1a).

### 3.4 Samples and methods

#### 3.4.1 Samples and sample preparation

A total of 23 clay-rich core samples usually shales or siltstones (see Xu et al., 2019; Li et al., 2020) has been collected from 18 wells drilled at several locations in the mid-western Ordos Basin at a depth interval between 1332.69 m and 2702.50 m (well positions are shown in Fig. 3.1b, Table 3.1). Macroscopically, the fine- to medium grained shale samples show fine lamination with alternating dark and lighter grey layers (Fig. 3.3).

Each sample was cut into two halves with a diamond rotation saw and subsequently dried at room temperature. One half was ground to fine powder as preparation for elemental carbon and sulfur analyses, Rock-Eval pyrolysis, and biomarker analysis. The second half was used to prepare polished sections for incident light microscopy. Polished sections were prepared on rock pieces cut perpendicular to bedding by following the procedures described in detail by Zieger and Littke (2019).

*Fig. 3.3. Photographs of selected representative core samples. See text for description.*

#### 3.4.2 Elemental carbon and sulfur analysis

TOC and TIC contents were measured on all samples using a liquid TOC II analyzer (Elementar). Aliquots of 100 mg powdered sample were first heated to 550 °C applying a heating rate of 300 °C/min and then kept isothermal for 600 s during which the TOC contents were measured. The temperature was then increased to 1000 °C and remained constant for 400 s to measure the TIC contents. TOC and TIC contents were measured with a non-dispersive infrared detector (NDIR) (detection limit 10 ppm;

TOC error 0.6%; TIC error 1.7%) by recording the amounts of carbon dioxide (CO<sub>2</sub>). The TS contents were measured by combusting 100 mg of powdered sample using a Leco S 200 sulfur analyzer (precision is <5% error, detection limit 0.001%). More detailed information on the devices and measuring procedures can be found in Prinz et al. (2017) and Grohmann et al. (2019).

#### 3.4.3 Rock-Eval pyrolysis

Rock-Eval pyrolysis was performed using a Rock-Eval VI instrument (Vinci Technologies) following the procedure described in detail in Behar et al. (2001).

The measured parameters including S<sub>1</sub> (volatile hydrocarbon content, mg HC/g rock), S<sub>2</sub> (remaining hydrocarbon generative potential, mg HC/g rock), S<sub>3</sub> (CO<sub>2</sub> formed by thermal breakdown of kerogen, mg CO<sub>2</sub>/g rock), and T<sub>max</sub> (temperature of maximum pyrolysis yield, °C) were used to calculate the hydrogen index (HI = S<sub>2</sub>/TOC, mg HC/g TOC), oxygen index (OI = S<sub>3</sub>/TOC, mg CO<sub>2</sub>/g TOC) and production index (PI = S<sub>1</sub>/(S<sub>1</sub> + S<sub>2</sub>)).

#### 3.4.4 Organic petrography

Maceral point counting was performed on a Zeiss Axio Imager incident light microscope operated with DISKUS Fossil software (Hilgers) both in white light and in a fluorescence mode at 500 times magnification (50×oil immersion objective). Before each vitrinite reflectance (VR<sub>r</sub>) measurement, a yttrium-aluminum-garnet standard (0.889% reflectance) was used to calibrate the instrument. 100 randomly oriented vitrinite particles were measured per sample whenever possible, according to ISO 7404-5. The maceral composition was determined based on the principles described in Taylor et al. (1998), with macerals being assigned according to the ICCP system 1994 (ICCP, 1998; ICCP, 2001; Pickel et al., 2017). On the same microscope, diameters of all present pyrite framboids were measured on 10 representative areas of 250 × 150 μm per sample by using a digital measuring device implemented in the Fossil software.

#### 3.4.5 Molecular geochemistry

Based on TOC contents, 4–6 g of pulverized sample was extracted by accelerated solvent extraction (ASE) with dichloromethane (DCM, 40 mL). Activated copper and sodium sulfate were used to reduce the elemental sulfur and water contents prior to fractionation. Extracts were separated into three fractions by column chromatography using an activated micro column packed with silica gel (2 g) and eluents of different polarity: 5 mL *n*-pentane for the aliphatic hydrocarbons and 5 mL *n*-pentane/DCM (40:60, v:v) for the aromatic hydrocarbons.

Gas chromatography (GC) was performed on aliphatic and aromatic fractions using a Fisons Instruments GC 8000 series, equipped with a flame ionization detector (FID), and a 30 m × 0.25 mm i.d Zebron ZB-1 fused silica column (0.25 μm film thickness). Hydrogen was used as carrier gas with a velocity of approx. 40 cm/s. Chromatographic conditions were set to 270 °C injector temperature, 1 μL split injection at an initial oven temperature of 60 °C, which was then programmed to 310 °C at a heating rate of 5 °C/min, with a final isothermal hold for 20 min.

The GC–MS analysis was performed using a quadrupol mass spec-trometer Trace MS (Thermoquest) linked to a Mega Series HRGC 5160 gas chromatograph (Carlo Erba, IT) equipped with a 30 m × 0.25 mm i. d. x 0.25 µm film Zebron ZB-5 fused silica capillary column. The MS was operated in electron ionization (EI+) mode with an ionization energy of 70 eV and an ion source temperature of 200 °C. Fragmentograms were obtained by selective ion monitoring (SIM) applying 11 and 14 different masses for aliphatic and aromatic fractions, respectively. Helium was used as carrier gas with a velocity of 30 cm/s. The chromatographic conditions for the aliphatic fraction were 270 °C injector temperature, 1 µL splitless injection (splitless time of 60 s) at 80 °C (isothermal time 3 min) then programmed at 10 °C/min to 160 °C, then heating to 320 °C with a rate of 3 °C/min, 20 min isothermal hold. For the aromatic fraction, the temperature program started at 80 °C (isothermal time 3 min), followed by heating to 320 °C at a rate of 3 °C/min, then keeping this temperature for 20 min.

All biomarker ratios were calculated from peak areas of specific ion chromatograms. Identification of individual compounds was based on the retention properties of standards and comparison of elution orders with published gas chromatograms. Evaluations were performed for terpanes ( $m/z$  191) and steranes ( $m/z$  217) in the aliphatic fraction as well as naphthalenes ( $m/z$  128 +142 +156 +170 +184), phenanthrenes (PHE,  $m/z$  178 +192 +206), dibenzothiophenes (DBT,  $m/z$  184 +198 +212), methylbiphenyls ( $m/z$  168), biphenyl (BP,  $m/z$  154), diphenylmethane (DPM,  $m/z$  168), and dibenzofurane (DBF,  $m/z$  168) in the aromatic fractions.

### 3.5 Results

#### 3.5.1 Elemental carbon and sulfur composition

The TOC contents of the samples range from 0.24% to 24.83% (mean value =2.72%, Table 3.1) and TIC and TS contents from 0.02 to 1.38% (avg. 0.24%) and 0.06 to 6.51% (avg. 0.65%), respectively (Table 3.1). Based on elemental carbon and sulfur contents, the three major sedi-mentary components including original OM (OM\* =OM before sulfate reduction), carbonate (CAR) and silicate (SIL) were calculated according to the following formulas originally presented by Littke (1993):

$$\text{CAR} = \text{TIC} \times 8.333, \text{ assuming that carbonate is present as calcite (3.1)}$$

$$\text{Corg}^* = \text{TOC} + 2 \times \text{TS} \times \text{MC/MS (3.2)}$$

$$\text{OM}^* = \text{Corg}^* \times 100/\text{COM (3.3)}$$

$$\text{SIL} = 100 - (\text{OM}^* + \text{CAR}) \text{ (3.4)}$$

Where Corg\* is the original organic carbon weight percentage prior to sulfate reduction; MC and MS are the molecular masses of carbon and sulfur, respectively; and COM corresponds to the carbon content of primary OM (here: 78%; Littke 1993). The results indicate that the analyzed shales are clearly dominated by silicates with values ranging from 50.4% to 98.87% (93.4% on average), whereas carbonate and OM\* contents range from 0.17 to 11.5% (avg. 2.0%) and from 0.56 to 38.1% (avg. 4.72%), respectively (Table 3.1).

### 3.5.2 Rock-Eval pyrolysis

Fig. 3.4. Plots of  $T_{max}$  versus HI (a) and PI (b), showing kerogen types and hydrocarbon potential for the samples from the Chang 7 Member.

Rock-Eval pyrolysis is generally used to evaluate kerogen characteristics including hydrocarbon generation potential, kerogen type, and thermal maturity (Fig. 3.4, Lafargue et al., 1998). For the samples studied,  $S_1$  and  $S_2$  values range from 0.13 to 3.70 (mean value = 0.89 mg HC/g rock) and from 0.62 to 92.50 (mean value = 8.46 mg HC/g rock; Table 3.2), respectively.  $S_3$  values range from 0.09 to 1.09 mg  $CO_2$ /g rock (0.27 on average). Hydrogen index (HI) values which are affected by the type and maturity of OM and, in turn, indicate the quality of kerogen, vary between 80 and 373 mg HC/g TOC with an average value of 177.  $T_{max}$  values of the studied samples range between 429 °C and 461 °C with an average of 445 °C indicating thermal maturity within the oil window. PI values, indicating both maturity and impregnation or migration loss for source rocks, vary from 0.04 to 0.48 (mean = 0.16).

### 3.5.3 Organic petrography

*Table 3.3.  $VR_r$  values, maceral compositions (percentages based on whole rock samples), and minimum (min.), maximum (max.) as well as average ( $\phi$ ) diameters of pyrite framboids of the Chang 7 Member samples. Std = standard deviation, sk = skewness, n = number of framboids measured.*

The analyzed samples are rich in autochthonous vitrinite particles which were used to measure vitrinite reflectance ( $VR_r$ ) and thus to assess thermal maturity.  $VR_r$  of the studied samples varies between 0.68% and 0.88%  $VR_r$  (0.77%  $VR_r$  on average, Table 3.3). The volumetric percentage of OM observed in the samples varies between 0.5 vol% (MW 16–1) and 38.8 vol% (MW 10–2). Sample MW 10–2 is especially rich in vitrinite (31.4 vol% of the whole rock, Table 3.3). Vitrinite particles (Fig. 3.5a) are abundant in all the samples analyzed, accounting for between 40.0% and 94.1% of the total macerals counted. The input of OM with terrestrial plant origin is further illustrated by the presence of inertinite in most samples (Fig. 3.5b and c), occurring as small detrital particles or in form of semifusinite or fusinite. Solid bitumen occurs either in-between mineral grains or as fillings of empty cell lumens in structured inertinite particles (Fig. 3.5c) and is observed almost in all samples, but not in high quantity. Liptinite is mainly submicroscopic, finely dispersed within the mineral matrix, showing a slight yellowish fluorescence. The liptinite macerals accounting for the determined volumetric percentages

are either liptodetrinite or lamalginite (Fig. 3.5d). A common feature of the samples are calcareous fossil shell remains with varying shapes. Some of these are perfectly round (Fig. 3.5e and f). Pyrite is abundant in all Chang 7 Member samples (Fig. 3.5a, c and e), occurring either as assemblages of recrystallized framboids (Fig. 3.5c, upper left corner), as framboidal pyrites surrounded by OM (Fig. 3.5a) or as euhedral crystals. The variation in sizes of pyrite framboids is large, with diameters ranging from around 2  $\mu\text{m}$  to > 40  $\mu\text{m}$  (6.0–14.9  $\mu\text{m}$  on average; Table 3.3).

Fig. 3.5. Photomicrographs representative of the organic matter in the Chang 7 Member source rocks under incident white light (a, b, c, e) and in fluorescence mode (d, f). Showing (a) vitrinite (V) with framboidal pyrite (P) (MW 1-2), (b) semifusinite (I) (MW 13), (c) fusinite (I) with solid bitumen (SB) filling empty cell lumens, (d) lamalginite (L) and finely dispersed liptinite within the mineral matrix, (e) circular, calcareous fossil remains in white light and (f) in fluorescence mode.

### 3.5.4 Molecular geochemistry

#### 3.5.4.1 Acyclic alkanes

Fig. 3.6. (a, b) Gas chromatograms; (c, d)  $m/z$  191 mass fragmentograms (hopanoids); (e, f)  $m/z$  217 mass fragmentograms (steranes) of the aliphatic fractions (samples MW 2 and MW 17), and (g) total ion chromatogram (TIC) of the aromatic fraction (sample MW 17). See Appendix (Table A3.1) for detailed peak identification.

Acyclic alkanes in the range of  $n$ -C<sub>9</sub> to  $n$ -C<sub>37</sub> are characterized by bimodal distributions in most samples (Fig. 3.6a and b), but some samples show unimodal distributions with higher proportions in the low- molecular weight  $n$ -alkanes (Fig. 3.7a) with maximum peaks occurring at  $n$ -C<sub>15</sub> and  $n$ -C<sub>17</sub> for most samples (Fig. 3.6a, b; Table 3.4).

*Table 3.4. Biomarker parameters of acyclic alkanes of the source rocks from the Chang 7 Member. Pr = pristane; Ph = phytane; CPI =  $2 \times \sum \text{odd } n\text{-C}_{23-29} / (\sum \text{even } n\text{-C}_{22-28} + \sum \text{even } n\text{-C}_{24-30})$ ; OEP =  $(n\text{-C}_{21} + 6 \times n\text{-C}_{23} + n\text{-C}_{25}) / (4 \times n\text{-C}_{22} + 4 \times n\text{-C}_{24})$ ; WI =  $\sum n\text{-C}_{21-31} / \sum n\text{-C}_{15-20}$ ; TAR =  $(n\text{-C}_{27} + n\text{-C}_{29} + n\text{-C}_{31}) / (n\text{-C}_{15} + n\text{-C}_{17} + n\text{-C}_{19})$ ; P<sub>aq</sub> =  $(n\text{-C}_{23} + n\text{-C}_{25}) / (n\text{-C}_{23} + n\text{-C}_{25} + n\text{-C}_{29} + n\text{-C}_{31})$ .*

MW 17	66	24	10	1.46	0.26	0.19	4.23	1.11	1.04	0.65	0.16	0.80
MW 18	87	10	3	3.63	0.43	0.15	12.23	1.11	1.03	0.29	0.05	0.84

CPI values (carbon preference index; Bray and Evans 1961) vary from 1.10 to 1.33 and OEP values (odd-to-even predominance; Peters and Moldowan 1993) range from 0.96 to 1.10 (Table 3.4). Pristane (Pr) and phytane (Ph) are the dominant acyclic isoprenoids. The Pr/Ph ratio ranges from 0.48 to 5.03 (Table 3.4; Peters et al., 2005). Their concentrations are in most cases lower than those of the adjacent  $n$ -alkanes, i.e. Pr/ $n$ -C<sub>17</sub> and Ph/ $n$ -C<sub>18</sub> values are in the range of 0.15–1.64 and 0.15–1.10, respectively (Table 3.4). The iso-alkanes norpristane and farnesane are also abundant in all samples (Figs. 6a, b). The  $n$ -C<sub>17</sub>/ $n$ -C<sub>27</sub> ratios, indicating the relative abundance of marine/aquatic over higher land plant derived OM (Eglinton and Hamilton 1967; Guenther et al., 2013; Rodrigues et al., 2016), varies from 0.75 to 28.08 (Table 3.4). Correspondingly, the terrigenous/aquatic ratio (TAR; Bourbonniere and Meyers, 1996) is lower than 1.00 (0.04–0.57) except for sample MW 16–1 (TAR = 1.09; Table 3.4). The proxy ratio on the relative input of submerged/floating macrophytes compared to phytoplankton plus higher land plants (P<sub>aq</sub>; Ficken et al., 2000) varies between 0.10 and 0.84 (0.72 on average, Table 3.4). The waxiness index (WI; Peters et al., 2005) reflecting the contribution of terrestrial plants to the OM ranges between 0.22 and 2.18 (Table 3.4).

Fig. 3.7. Ternary diagrams showing (a) the *n*-alkane distributions and (b) the proportions of phenanthrene (PHE), dibenzofuran (DBF), and dibenzothiophene (DBT) of the Chang 7 Member samples.

#### 3.5.4.2 Terpanes

Tricyclic terpanes ( $C_{19}$ - $C_{26}$  Tri),  $C_{24}$  tetracyclic terpene ( $C_{24}$  Tet) and pentacyclic terpanes (hopanes) are widely distributed in all samples (Fig. 3.6c and d). The concentrations of  $C_{19}$  Tri and  $C_{24}$  Tet show large variations compared to the  $C_{19}/C_{23}$  Tri and the  $C_{24}$  Tet/( $C_{24}$  Tet +  $C_{23}$  Tri) ratios, ranging from 0.23 to 2.42 and from 0.19 to 0.72, respectively (Table 3.5). The  $C_{22}/C_{21}$  Tri (0.15–3.32) and the  $C_{24}/C_{23}$  Tri (0.47–0.87) ratios are rather variable (Table 3.5). Large variations between the samples are further observed in the ratio of  $C_{26}/C_{25}$  Tri (1.03–7.83).

The Ts/(Ts + Tm) ratio, applied as a thermal maturity parameter (Seifert and Moldowan 1978), ranges from 0.24 to 0.90. Besides Ts, other diahopanes, especially  $C_{30}$  diahopane ( $C_{30}^*$  DH), are observed in the source rocks studied (Fig. 3.6c, d). Nor-moretane ( $C_{29}$  M) and moretane ( $C_{30}$  M) are thermally less stable than  $C_{29}$  nor-hopane ( $C_{29}$  H) and  $C_{30}$  hopane ( $C_{30}$  H) (George et al., 2001). The ratios of  $C_{30}$  H/( $C_{30}$  H +  $C_{30}$  M) (0.89–0.95) and of  $C_{29}$  H/( $C_{29}$  H +  $C_{29}$  M) (0.81–0.94) are close to or even exceed the respective equilibrium level (George et al., 2001). The Gam content is generally low as reflected by Gam/ $C_{30}$  hopane ratios < 0.20 (Fig. 3.6c and d, Table 3.5).

The 22S/(22S + 22R) ratios for  $C_{31}$  and  $C_{32}$  homohopanes range from 0.44 to 0.61 and from 0.56 to 0.65, respectively (Table 3.5).

$C_{30}$  H is more abundant than  $C_{31}$  22R hopanes; i.e. ratios of  $C_{31}$  22R/  $C_{30}$  hopane (0.11–0.42) are <1 for the samples analyzed (Fig. 3.6c and d; Table 3.5). The samples are characterized by low  $C_{35}$  homohopane contents as indicated by homohopane index values (HHI,  $C_{35}/\Sigma C_{31-35}$  22S and 22R homohopanes; Peters and Moldowan 1991) and  $C_{35}/C_{34}$  22S and 22R homohopane ratios of less than one (Table 3.5).

**Table. 3.5 Biomarker parameters of tricyclic and tetracyclic terpanes, hopanes, and steranes of the source rocks from the Chang 7 Member in the mid-western Ordos Basin. Tri = tricyclic terpanes, Tet = tetracyclic terpanes, H = hopane, DH = dihopane, M = moreane, Gam = Gammacerane; HHI = homohopane index, steranes/hopanes =  $C_{27}$ - $C_{29}$  regular steranes/ $C_{29}$ - $C_{35}$  17 $\alpha$ -hopanes.**

#### 3.5.4.3 Steroids

The concentration of steranes is lower than that of hopanes with the steranes/hopanes ratio ranging from 0.13 to 0.61 (Table 3.5). The sterane distributions are shown in Fig. 3.6e and f; they are characterized by higher proportions of C<sub>29</sub> (41–71%) compared to C<sub>27</sub> (14–35%) and C<sub>28</sub> (9–31%)  $\alpha\alpha\alpha$  20R steranes (Table 3.5). The C<sub>29</sub>  $\alpha\alpha\alpha$  20S/(20S + 20R) ratio (Seifert and Moldowan 1986) ranges from 0.38 to 0.61 (Table 3.5).

The C<sub>29</sub>  $\beta\beta$ /( $\beta\beta$  +  $\alpha\alpha$ ) ratio ranges from 0.42 to 0.60 (Table 3.5). Equilibrium point for this ratio is reached at values of 0.67–0.71 corresponding to around 0.9% VR<sub>r</sub> (Seifert and Moldowan 1986).

C<sub>27</sub> diasteranes are recognized in all samples but their abundances show large variations; the C<sub>27</sub> diasteranes/(diasteranes + regular steranes) ratio varies from 0.15 to 0.43 (Fig. 3.6e and f; Table 3.5). Sample MW 17, for example, with a high abundance of C<sub>27</sub> diasteranes also shows a marked contribution of short-chain C<sub>21</sub>–C<sub>22</sub> steroids (pregnane and homopregnane) in comparison to sample MW 2 (Fig. 3.6e and f). Pregnane is here more abundant than homopregnane with pregnane/homopregnane ratio values ranging from 1.72 to 4.24 (Table 3.5).

#### 3.5.4.4 Aromatic hydrocarbons

The selected mass fragmentograms of the aromatic fraction from sample MW 17 are exemplarily shown in Fig. 3.6g. The samples are characterized by the predominant presence of 2-methylnaphthalene (2-MN), phenanthrene (PHE) and/or trimethylnaphthalenes (TMNs), whereas the proportions of sulfur-containing compounds such as dibenzothiophene (DBT) are low (DBT/PHE ratios are 0.01–0.14; Table 3.6).

The distributions of methylnaphthalenes, ethylnaphthalene (EN) and dimethylnaphthalene (DMN) isomers show that 1-MN is less abundant than 2-MN in all samples (Fig. 3.6g). There is a predominance of 2-EN over 1-EN. The most predominant compound in the TMN homologues is 1,3,6- TMN, while 1,2,4-TMN and 1,4,5-TMN have the lowest abundances in most samples. The tetramethylnaphthalenes (TeMNs) distribution is characterized by the predominance of 1,3,6,7-TeMN and 1,2,5,7- + 1,3,6,8-TeMN. The methylphenanthrenes (MPs) distribution indicates that 9-MP is dominant while a predominance of 2-MP can be observed in some samples. With respect to dimethylphenanthrenes (DMPs), the studied samples are characterized by a relatively high abundance of 1,3- + 3,9- + 3,10- + 2,10-DMP. The distribution of methylbiphenyls (MBPs) in all samples is similar: 3-MBP is most abundant followed by 4-MBP. The distribution of dimethyldibenzothiophenes (DMDBTs) shows that 3,6- DMDBT is present in relatively high amounts in most samples, but 2,7- + 3,7- + 2,8-DMDBT or 4,6-DMDBT are predominant in individual samples such as MW 2, MW 7 and MW 11–2.

The normalized distribution of PHE, DBF, and DBT shows that PHE occurs in highest relative concentration (71.63%–91.63%) followed by DBF (2.42%–23.15%) and DBT (3.43%–10.95%) (Fig. 3.7b; Table 3.6).

 MBPR: methylbiphenyl ratio (3-MBP/2-MBP). Alexander et al., 1986.  
 MDR: methyl dibenzothiophene ratio (4-MDBT/1-MDBT). Radke et al., 1986.  
 $VR_{MDR}$ : calculated reflectance from MDR ( $0.073 \times MDR + 0.51$ ). Kvalheim et al., 1987.  
 DMDR: dimethyldibenzothiophene ratio (4,6-DMDBT/[3,6- + 2,6-DMDBT]). George et al., 2001.  
 DMPR: dimethylphenanthrene ratio ( $[3,5- + 2,6- + 2,7-DMP]/[1,3- + 3,9- + 2,10- + 3,10- + 1,6- + 2,9- + 2,5-DMP]$ ). Radke et al., 1982.  
 $VR_{DMPR}$ : calculated reflectance from DMPR ( $1.17 \times \log_{10} DMPR + 1.14$ ). Radke 1984.

Moreover, trimethylphenanthrenes (TMPs,  $m/z = 220$ ); 4-ring polycyclic aromatic PAHs including fluoranthene and pyrene ( $m/z = 202$ ), methylfluoranthenes, benzo[a]fluorene, benzo[b]fluorene, 2-methylpyrene, 4-methylpyrene and 1-methylpyrene ( $m/z = 216$ ); 5-ring PAHs including chrysene ( $m/z = 228$ ); benzo[e]pyrene, benzo[a] pyrene, and perylene ( $m/z = 252$ ); and 6-ring PAHs including indeno [1,2,3-cd]pyrene and benzo[ghi]perylene ( $m/z = 276$ ) are observed (Appendix Figure A.3.1).

Various specific aromatic indices which are representative of plant species, depositional environment, and thermal maturity are given in Table 3.6 and are discussed in more detail in the following sections.

### 3.6 Discussion

#### 3.6.1 Paleo-depositional environment

The TOC/TS ratios in the Chang 7 Member indicate a non-marine/ freshwater depositional environment (Fig. 3.8; after Berner 1984), which is consistent with other data, such as high  $C_{26}/C_{25}$  Tri ratios and low  $C_{31} 22R/C_{30} H$  ratios (Peters et al., 2005; Table 3.5). The low amount of gammacerane along with Pr/Ph ratios  $>1$  (except for the samples from MW 16 well; Table 3.4) further indicate freshwater conditions without any salinity stratification during the deposition of the Chang 7 Member (ten Haven et al., 1987; Sinninghe Damsté et al., 1995a; Peters et al., 2005). The relatively low  $C_{28}$  steroid proportion is typical of limnic environments (Volkman, 1986; Peters et al., 2005) and the low steranes/hopanes ratio of  $<1$  (Peters et al., 2005) is in agreement with the above stated findings. The high abundance of DBF compared to both DBT (Fan et al., 1990, 1991) and MDBTs (Hughes 1984) as well as the predominance of MPs over MDBTs (Radke et al., 2000) also indicates that the studied samples were deposited under conditions not affected by marine waters. The presence of sufficient iron, limiting the sulfurization of OM can be visualized by comparing TS values and DBT/PHE ratios (Fig. 3.9a; Song et al., 2017). The low organic sulfur contents as reflected by low DBT/PHE ratios of the Chang 7 Member shales (Table 3.6) can be explained by the low sulfurization of OM due to the presence of iron leading to the utilization of sulfur in the formation of pyrite, which is typically most pronounced in freshwater containing little sulfate. Such pattern is often observed in clay-rich source rocks while high organic sulfur contents have been reported for carbonate source rocks (Rullkötter et al., 1990; Hughes et al., 1995; Barakat and Rullkötter, 1999; Grohmann et al., 2019).

Applying the paleo-depositional plot after Hughes et al., (1995), which sets the amount of organic sulfur in relation to the OM's origin, allows for the classification of depositional setting based on data from well-studied source rocks. Fig. 3.9b shows that the analyzed samples of the Chang 7 Member plot in the sulfate-poor environments typical for shales deposited as lake sediments. However, Pr/Ph ratios reveal some differences for the sample-set analyzed in this study. Samples taken from the well drilled in the central part of the former lake (MW 16 well) show distinctly lower values than those originating from wells further north (MW 1 and MW 2 wells; Figs. 1b, 9b) which show fluvio-deltaic characteristics.

Fig. 3.8. TS vs. TOC indicating depositional environments of the Chang 7 Member source rocks. Data of normal marine sediments and Black Sea sediments from Berner and Raiswell, 1983 and Leventhal 1983, respectively.

Unlike in marine environments where the TOC content is commonly negatively related to the carbonate content but shows positive correlation to silicate contents (Sachse et al., 2012a; Bou Daher et al., 2015; Ghassal et al., 2018), organic-rich shales which are dominated by silicate minerals with sufficient nutrient supply often show a positive relationship between TOC values and carbonate contents (Rippen et al., 2013). In the shales of the Chang 7 Member, Corg\* shows an unclear relationship with CaCO<sub>3</sub> content (both calculated from measured TOC, TS and TIC), indicating that calcareous plankton/bacteria had only little contribution to the OM (Appendix Figure A3.2).

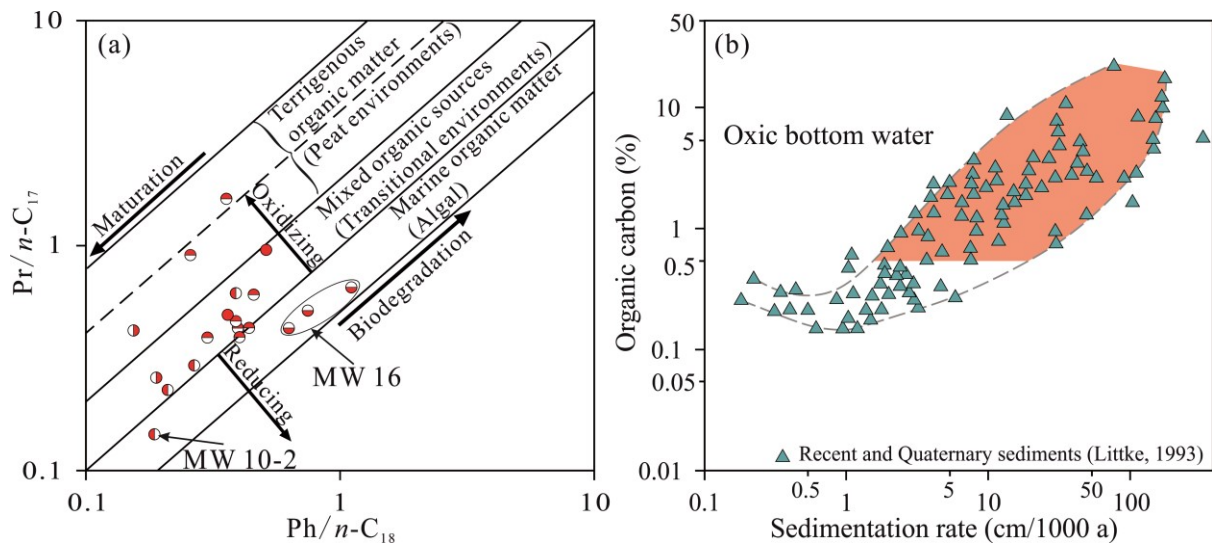

Fig. 3.9. Plots of pristane/ $n$ -C<sub>17</sub> vs. phytane/ $n$ -C<sub>18</sub> reflecting kerogen type, maturity, and depositional environment (after Shanmugam, 1985) (a) and organic carbon content vs. sedimentation rate (modified after Littke, 1993) (b). The range of sedimentation rates for the Chang 7 member samples is marked by the red area.

Oxygenated bottom water depositional conditions are supported by the high Pr over Ph ratios (Didyk et al., 1978) in most areas except the central part of the studied part of the Ordos Basin, represented by sample MW 16 (Fig. 3.1c). The ratio is related to different anaerobic and aerobic degradation pathways of the chlorophyll side-chain, but should always be used in combination with

other redox proxies, such as TOC/TS ratios (Sachse et al., 2011; Rippen et al., 2013; Song et al., 2014; Ghassal et al., 2018). An oxygenated and/or sulfate-depleted depositional environment is further indicated by high TOC/TS ratios (1.35–21.17; Fig. 3.8) as well as very low values of HHI and  $C_{35}/C_{34}$  22S and 22R homohopane (Table 3.5; Köster et al., 1997; Peters et al., 2005; Sachse et al., 2012b). Classically, the occurrence of  $C_{30}^*$  DH ( $C_{30}^*$  DH/ $C_{30}$  H ratios are 0.06–1.42; Table 3.5) indicates deposition in clay-rich settings under oxic or suboxic conditions (Nytoft et al., 2006; Li et al., 2009; Baydjanova and George 2019). Such a depositional environment is also demonstrated by the positions of the analyzed samples in the Pr/ $n$ - $C_{17}$  vs. Ph/ $n$ - $C_{18}$  diagram (Fig. 3.10a). The samples NW 10–2 and NW 16 close to the field of reducing conditions in Fig. 3.10a also show the highest HI values.

Fig. 3.10. Results of the pyrite framboids size distribution showing (a) mean framboid diameters vs. standard deviation and (b) skewness of diameter distribution (plot after Wilkin et al., 1996).

The presence of large framboidal pyrites (Figs. 5a, 11) with a general skewness towards larger diameters and framboidal pyrite aggregation (Figs. 5c, e) are further indicators of rather oxic conditions during the sedimentation of the Chang 7 Member shales (Wilkin et al., 1996). These framboidal pyrites can be observed in almost all samples except samples MW–12 and MW–13 (Fig. 3.11). The rather large framboidal pyrites as well as fine, dot-like pyrites inserted in or next to OM (Fig. 3.5a) indicate a formation during local reducing conditions caused by oxygen depletion via OM degradation at the early diagenesis stage (Canfield et al., 1992). Similar findings on shales from the Chang 7 Member have been made on other samples from the southwestern Ordos Basin by Yuan et al. (2017), who reported average diameters of 10.6 μm to 13.8 μm.

The paleo-redox conditions concluded from the data presented here are in line with findings made by Chen et al. (2019a) who also indicated sub-oxic to oxic conditions during the formation of organic-rich shales of the Chang 7 Member based on the isotopic composition of nitrogen.

Usually, in oxic to sub-oxic sub-aquatic environments, a high concentration of well preserved OM can only occur in rather calm waters and at high sedimentation rates (Meyers and Ishiwatari 1993; Pichevin et al., 2004). The relationship between organic carbon content and sedimentation rate in recent and Quaternary sediments is shown in Fig. 3.10b (Littke 1993). For the Chang 7 Member samples, considering the original organic carbon content (see eq. 1), sedimentation rates ranging from at least 1.5 cm/1000 years to more than 1 m/1000 years are expected (red area in Fig. 3.10b). This is consistent

with the large range between moderate to high sedimentation rates suggested by Chen et al. (2019b) for the Chang 7 Member in the Triassic Ordos Basin. The low HHI values and the decreasing trend from C<sub>31</sub> to C<sub>35</sub> homohopane contents further support a clastic depositional environment for the Chang 7 Member (Peters and Moldowan 1991; Sinninghe Damsté et al., 1995; Waseda and Nishita 1998).

Fig. 3.11. Dibenzothiophene/phenanthrene ratio vs. TS values (after Song et al., 2017) (a) and Pr/Ph (after Hughes et al., 1995) (b), reflecting depositional environment and lithology of the Chang 7 Member samples.

### 3.6.2 Origin of organic matter

Microscopy data shows that the OM in the Chang 7 Member is mainly composed of fragments (from about 1 to >200  $\mu\text{m}$ ) of fusinite and vitrinite (Fig. 3.5a-c) with a small number of algae-derived OM, mainly in form of lamalginite (L) and finely dispersed liptodetrinite within the mineral matrix (Fig. 3.5d). Comparing the volumetric percentages of counted macerals with TOC values, it gets obvious that almost all OM is visible in the form of macerals and very little is submicroscopically small. This observation is in accordance with the classification of OM as type II-III kerogen derived from Rock-Eval results (Fig. 3.4a). The contribution of terrestrial derived OM to the Chang 7 Member shales has been reported before, as palynomorphs including bisaccate pollen and an *Asseretospora-Walchiites* assemblage (Ji and Meng, 2006; Ji et al., 2010).

On the other hand, the studied samples are characterized on a molecular level by the predominance of short-chain alkanes ( $n\text{-C}_{10-20}$ ) with  $n\text{-C}_{17}$  and  $n\text{-C}_{18}$  being most pronounced, which is typically attributed to algae and cyanobacteria (Hunt 1996), while the relative contribution of long-chained  $n$ -alkanes ( $n\text{-C}_{26-35}$ ) derived from waxes of higher land plants (Eglinton and Hamilton 1967; Killops and Killops 2005) is relatively low. Further, the high proportion of short-chain  $n$ -alkanes and the absence of an unresolved complex mixture in gas chromatograms (Fig. 3.6a, b) indicate that no significant biodegradation took place (Hedges et al., 2000; Song et al., 2015a; Ghassal et al., 2018). Only minor terrigenous input of OM is expected based on the  $n\text{-C}_{17}/n\text{-C}_{27}$  ratios and TAR values (Brooks et al., 1969; Connan and Cassou, 1980; Bourbonniere and Meyers, 1996), and only some of the samples show moderate to high (>0.8) WI values which are used as a proxy of a substantial contribution of terrestrial OM (Table 3.4). The high Paq values (>0.4; Table 3.4) related to the concentrations of mid molecular

weight *n*-alkanes (*n*-C<sub>21–25</sub>) and the second-largest peak of *n*-C<sub>23</sub> and *n*-C<sub>25</sub> in part of the samples (Fig. 3.6a, b) indicate that submerged macrophytes indeed contributed to the accumulated OM. Fig. 3.6a and b indicates that emergent aquatic plants (typically producing C<sub>25</sub>, C<sub>27</sub> or C<sub>29</sub> *n*-alkanes during diagenesis) and conifers (C<sub>27</sub> or C<sub>29</sub> *n*-alkanes) are relatively more important than other woody terrestrial vegetation and mangroves (typically producing C<sub>29</sub>, C<sub>31</sub> or C<sub>33</sub> *n*-alkanes; He et al., 2020). However, these conclusions drawn by the evaluation of GC-FID data should be taken with caution, since the *n*-alkane distribution is easily affected by maturity (Peters et al., 2005). Furthermore, the source information from *n*-alkanes is not always conclusive due to their relatively simple structure and the complexity of other components present in waxes (Kolattukudy 1976). For example, the extracts of conifer waxes show *n*-alkanes varying between C<sub>16</sub> and C<sub>35</sub> with peak carbon varying from C<sub>23</sub> to C<sub>33</sub> (Oros et al., 1999), and terrigenous OM producing predominantly short chain *n*-alkanes has been observed in some immature to early mature Codó Formation samples in the São Luís Basin in Brazil (Gonzales et al., 2020). Finally, CPI values of the samples studied here (Table 3.4) are consistent with terrestrial OM input, if the maturity stage is considered. Thus, the distribution of *n*-alkanes (e.g. Fig. 3.6a) fits well with type II-III kerogen. In fact, for the samples analyzed here, petrographic data (maceral composition; Table 3.3) and only moderate HI values not exceeding 400 mg HC/g TOC (Table 3.2) do not support such conclusions; the same holds true for the low sterane/hopane ratios (Table 3.5). Steranes originate mainly from algae and higher plants, and hopanes originate from the cell material of bacteria (Rohmer and Ourisson 1976). In samples dominated by terrigenous OM, there is commonly also a high amount of (submicroscopic) bacterial biomass; therefore sterane/hopane ratios are low. The presence of steranes and diasteranes is further regarded as evidence for eukaryotic input (cf. Summons et al., 2006). A predominance of C<sub>27</sub> steranes is characteristic of algal input (Volkman, 2003), whereas a strong contribution of C<sub>29</sub> steranes is usually associated with terrestrial higher plant (Huang and Meinschein, 1979; Moldowan et al., 1986; Volkman, 2003). As shown in Fig. 3.12a, most samples are characterized as clay-rich source rocks deposited under oxic conditions with significant terrigenous OM input. The ternary diagram of the C<sub>27</sub>, C<sub>28</sub> and C<sub>29</sub>  $\alpha\alpha\alpha$  20R steranes distributions (Fig. 3.12b; Huang and Meinschein 1979) indicates a mixed OM origin from algae, higher land plants and bacteria deposited in a terrestrial environment. Samples interpreted to be deposited under bay/estuary environments are mainly concentrated in the northwestern study area, such as samples MW 1–1, MW 4, and MW 7 (planktonic/bacterial; Fig. 3.12b). High proportions of C<sub>19</sub> and C<sub>20</sub> Tri further point towards a substantial terrestrial OM input into the basin (Peters et al., 2005), whereas C<sub>23</sub> Tri is predominant in a reducing marine carbonate settings with high contribution of marine OM (Waples and Machihara, 1991; Tao et al., 2015). Large variations of C<sub>19</sub>/C<sub>23</sub> Tri and C<sub>24</sub> Tet/(C<sub>24</sub> Tet + C<sub>23</sub> Tri) ratios are indicative of a mixed lacustrine aquatic algal-bacterial and terrestrial OM, which is consistent with the low to moderate ratios of C<sub>24</sub>/C<sub>23</sub> Tri and low of C<sub>22</sub>/C<sub>21</sub> Tri (Table 3.5) (Peters and Moldowan, 1993; Preston and Edwards, 2000; Peters et al., 2005; Volk et al., 2005; Adegoke et al., 2014).

Fig. 3.12. Plot of (a)  $C_{21-22}/(C_{21-22} + C_{27-29})$  sterane vs.  $C_{27}$  diasteranes/(diasteranes + regular steranes) (modified after Wang et al., 2015) and (b) ternary diagram showing the distribution of  $C_{27}$ ,  $C_{28}$  and  $C_{29}$  steranes (modified after Huang and Meinschein, 1979).

Aromatic hydrocarbons such as 1,7-DMP, 1-MP, and 1,2,5-TMN can originate from conifers, such as Araucariaceae resins (Alexander et al., 1988). Such species might have been the primary source for the terrestrial OM input into the paleo-lake during the deposition of the Chang 7 Member. The high abundances of these compounds in analyzed shales indicate a strong contribution of coniferous plant species (Fig. 3.6g). This interpretation is consistent with the assumption that forests surrounding the area were indeed dominated by conifers in the mid-latitudes of eastern Asia during the Late Triassic–Early Jurassic (Pole et al., 2016). In addition, the palynoflora was found to be dominated by bisaccate pollen produced by conifers in the Yanchang Formation (Ji and Meng, 2006). Additionally, values of the  $\log(1,2,7\text{-TMN}/1,3,7\text{-TMN})$  ratio (see Table 3.6) suggest a lack of contribution of plant matter originated from angiosperm species (Strachan, 1988), which is in agreement with the biological evolution suggested for the surrounding area at the time of the formation of the Chang 7 Member. However,  $\log$  ratios of 1-MP/9-MP, 1,2,5-TMN/1,3,6-TMN and 1,7-DMP/(1,3- +3,9- +2,10- +3,10-DMP) which were used as indicators of OM input from coniferous higher plants are well below the threshold values suggested by Alexander (1988) (Table 3.6). This might be explained by the vulnerability of these parameters to thermal alteration (van Aarssen et al., 1999; Arouri and McKirdy, 2005), lithology or OM sources (Grice et al., 2007; Alexander et al., 1995; van Aarssen et al., 1999). The presence of abundant 1,6-DMN, 1,2,5-TMN and 1,7-DMP is further prove of land plant OM input (Romero-Sarmiento et al., 2011). These compounds show high abundances in the Chang 7 Member sam-ples (Fig. 3.6g), and the presence of abundant naphthalene, TMPs, chrysene and perylene, etc. are typically indicative of terrigenous higher plant input (Chaffee and Johns 1983; Chaffee and Fookes 1988). The terrestrial nature of the OM is further indicated by PHE relative abundances (compared to DBF and DBT) exceeding 70% (Table 3.6 and Fig. 3.7b; Radke et al., 2000).

The occurrence of PAHs including pyrene, fluoranthene, and chrysene can be related to the significant presence of fusinite macerals, most particularly pyrofusinite, in the OM (Romero-Sarmiento et al., 2011). Inertinite contents of 10.3% on average (on a mineral matter-free basis, calculated from Table 3.3), presented by mainly structured, oxidized particles (Figs. 5b,c) in the samples analyzed here, combined with the identification of compounds such as benzo[a]pyrene, benzo[e]pyrene, benzo[b]fluoranthene, perylene, indeno[1,2,3-cd]pyrene, and benzo [ghi]perylene indicate that wildfires occurred close to the examined area (Killops and Massoud 1992; Lima et al., 2005; Huang et al., 2015; Jar-oszewicz et al., 2018). These events may be partly related to frequent volcanic eruptions that reportedly occurred during the corresponding period of the Chang 7 member deposition in the Qinling Mountain area in the southern part of the basin (Fig. 3.1b; Zhang et al., 2017, Zhang et al., 2020). Moreover, the in part high OM contents of the Chang 7 shales may also be related to re-occurring volcanic eruptions and volcanic ash, promoting the prosperity of bacteria and algae resulting in an increased primary bio-productivity (Erbacher et al., 1996; Duggen et al., 2007; Olgun et al., 2013). In summary, the source-related characteristics of the Chang 7 Member samples indicate a strong contribution of terrestrial-derived OM, to a great extent originating from gymnosperms (conifers) as well as the contribution of algal-bacterial-macrophytic OM deposited at rather high sedimentation rates in a siliciclastic lake environment. Proxies for redox conditions reveal a sulfate poor-lacustrine environment in the central part of the basin (MW 16 well) and fluvio-deltaic environments northwestward (MW 1 well). The central part of the study area (location of MW 16 well) shows slightly more reducing bottom water characteristics during deposition (Figs. 1b, 8, 10a).

### 3.6.3 Thermal maturity and source rock characteristics

The  $VR_r$  and Rock-Eval  $T_{max}$  values (Fig. 3.13a) indicate a maturity of the samples within the oil window, while the shales have not yet reached 50% conversion to petroleum (Fig. 3.4). This interpretation is consistent with the following molecular thermal maturity parameters derived from data of the aliphatic as well as aromatic fractions. A comparison of the ratios of  $C_{29} \alpha\alpha\alpha / (20S + 20R)$  and  $C_{29} \beta\beta / (\beta\beta + \alpha\alpha)$  as well as of the terpane ratios of  $C_{31}$  and  $C_{32}$  homohopanes  $22S / (22S + 22R)$  illustrate a thermal maturity between the early and main oil window (Fig. 3.13b and c; Peters et al., 2005). Similar maturity conditions can be recognized from the plots of  $C_{29} \alpha\beta / (\alpha\beta + \beta\alpha)$  hopane vs.  $C_{30} \alpha\beta / (\alpha\beta + \beta\alpha)$  hopane and CPI vs. OEP (Fig. 3.13d, e). The steroid pregnane has a higher abundance than homopregnane (Fig. 3.6f), which is consistent with a peak oil window maturity (George et al., 2008). This relatively homogeneous maturity over a wide area corresponds to the rather equal thickness of the Triassic Yanchang Formation along the whole Yishan Slope (Fig. 3.1c) and later a rather consistent burial over large areas during the Jurassic and Early Cretaceous. The ratio of  $Ts / (Ts + Tm)$  vs.  $C_{27}$  diasteranes / (diasteranes + regular steranes) (Fig. 3.13f) may indicate a larger variability of maturity, but both parameters can be affected by variations in the OM facies (Farrimond et al., 1998; Song et al., 2015b; Peters et al., 2005; Sachse et al., 2011; Baniasad et al., 2017).

Fig. 3.13. Rock-Eval  $T_{max}$ , vitrinite reflectance and molecular thermal maturity indicators of the Chang 7 Member samples. (a)  $T_{max}$  vs.  $VR_r$ , (b)  $C_{29} \text{ aaa } 20S/(20S + 20R)$  vs.  $C_{29} \beta\beta/(\beta\beta+\alpha\alpha)$ , (c)  $C_{31}$  homohopane  $22S/(22S + 22R)$  vs.  $C_{32}$  homohopane  $22S/(22S + 22R)$ , (d)  $C_{29} \alpha\beta/(\alpha\beta+\beta\alpha)$  hopanes vs.  $C_{30} \alpha\beta/(\alpha\beta + \beta\alpha)$  hopanes (after George et al., 2001), (e) CPI vs. OEP, and (f)  $Ts/(Ts + Tm)$  vs.  $C_{27}$  diasteranes/(diasteranes + regular steranes). E.L. equiv. = equilibration levels equivalent to vitrinite reflectance values (taken from Peters et al., 2005).

Aromatic maturity parameters including MPI-1 (Radke and Welte, 1983), TNR-2 (Radke et al., 1994) and MDR (Radke et al., 1986) (Table 3.6) indicate that the samples are at the main stage of oil generation, while TMNR, TeMNR-1, TeMNR-2 and DMPR indicate somewhat lower, early to peak oil window maturities (Table 3.6; van Aarssen et al., 1999; George and Ahmed, 2002) which is in better agreement with the  $VR_r$  and Rock-Eval  $T_{max}$  data. The MBPR is based on published calibrations (Cumbers et al., 1987) and the low values of DMDR based on MDBT are consistent with early to peak oil window maturities (Radke 1988; George and Ahmed, 2002). The TNR-1 and MPDF ratios also

indicate a peak to late oil window maturity (George and Ahmed, 2002). In summary, various aromatic indicators show slight discrepancies, although all values are in line with an oil window maturity (George and Ahmed 2002).

In summary, the thermal maturity data are remarkably uniform within the early oil window stage, although the samples were taken from the entire, large western Ordos Basin. Obviously, burial history within this area was quite consistent, affecting marginal and central parts in a similar way.

Regarding their moderate to very high TOC contents and HI values, most samples are characterized as good to excellent source rocks, while few samples have poor to fair source rock potential (TOC content <1.0% and  $S_1 + S_2$  content <6 mg/g). The quality of the source rocks is not as good as previously reported (e.g. Xu et al., 2019), which might be caused by the sampling locations further towards the margin of the basin. Best source rock properties are expected in the area of the former central lake.  $T_{max}$  values and PI ratios (Table 3.2, Fig. 3.4b) imply that most samples can be considered as well-drained source rocks which expelled generated hydrocarbons efficiently to the coarse grained sandstone/siltstone intervals nearby (Raji et al., 2015). Unlike other samples, MW 6 and MW 16–1 have lower  $T_{max}$  but high PI values (Fig. 3.4b), which might be caused by natural or artificial impregnation. Moreover, high PI values can be caused by the early generation of hetero-compounds (Curiale, 1986), which decrease with increasing thermal maturity (Lewan, 1994). In a poorly-drained system, expelled hydrocarbons can impregnate the coarser grained laminae (Jarvie 2012; Chen and Jiang 2016; Li et al., 2018). In general, the Chang 7 Member is a clay-rich shaly rock (clay mineral contents of more than 40%), where sandstone intervals occur in direct vicinity within the same member and have been proven as important tight-oil reservoirs (Cui et al., 2019; Xu et al., 2019). The shaly intervals might also act as potential shale-oil reservoirs (Chen et al., 2019b).

### 3.7 Conclusions

This study presents new data on organic geochemistry, elemental carbon and sulfur composition, Rock-Eval pyrolysis and organic petrography on the Triassic Chang 7 Member in the Yanchang Formation, an important petroleum source rock in the mid-western Ordos Basin, China. Samples from 18 different wells have been studied in order to achieve an overview on regional heterogeneity over a large area. Thus, this study gives insight into variability of resource potential, paleo-depositional environment, as well as origin and maturity of organic matter.

Multiple parameters, such as TOC/TS, sizes of pyrite framboids and molecular biomarker data indicate that the Chang 7 member is a typical clay-rich source rock deposited and preserved in a sulphate-poor lacustrine environment in the center of the basin (MW 16 well) and a fluvio-deltaic environment northwestward (MW 1 well) under fresh water and oxic to sub-oxic conditions. The MW 16 well situated close to the center of the former lake shows, however, slightly reducing conditions. Organic matter is composed of a Type II-III kerogen. A mixture of lacustrine aquatic algal-bacterial-

macrophytic organisms and terrigenous higher plants (mainly composed of conifers) was the main source of organic matter based on combined organic petrography and biomarkers results.

The thermal maturity of the Chang 7 Member source rocks reaches the main phase of oil generation based on vitrinite reflectance, Rock-Eval and most molecular geochemical data. This small range of maturity accords with the thickness distribution of the Triassic, Jurassic and Lower Cretaceous rocks in the study area. The study reveals that these source rocks possess good to very good potential for liquid hydrocarbon generation, based on the moderate to very high total organic matter content, thickness (up to 100 m of source rock within the 60–120 m Chang 7 Member) and Rock-Eval results.

## **4 High microbial gas potential of Pleistocene lacustrine deposits in the central Qaidam Basin, China**

### **4.1 Abstract**

Thick Pleistocene fine-grained rocks in the central Qaidam Basin, China, are regarded as the principal source rocks for microbial gas there. Here, for the first time, a detailed investigation on the organic geochemistry and petrology of this sedimentary sequence is presented. Two different, immature, lacustrine source rocks facies are present in the study area. Organic facies A samples with high TOC (4.1–25.3 wt%) and TS (1.5–3.7 wt%) contents mainly developed under a suboxic to anoxic freshwater column at the lake margins. This shallow water fluviolacustrine facies, accounts for only a small proportion of the whole sedimentary sequence, but has the highest petroleum generation potential. In contrast, organic facies B samples having lower TOC (0.5–1.1 wt%) and TS (0.14–1.0 wt%) contents were deposited in a more oxic, brackish-lacustrine water body. However, exceptionally, anoxic conditions were present in sediments that were sealed by algae mats.

The majority of the interval is comprised of gas prone, mixed type II-III kerogen derived mainly from aquatic plants. Organic facies A is interpreted to be derived from abundant macrophytes (e.g. non-marine algae, submerged angiosperms) around the lake margin. By contrast, the organic matter in organic facies B mainly stems from saltwater algae, with some additional bacterial contribution. Terrestrial higher plants are subordinate in both organic facies. The organic carbon accumulation rate was high compared to organic matter-rich Quaternary marine sediments. Cold and dry climate conditions and high burial rates favored methanogenesis via carbonate reduction in the sediments.

### **4.2 Introduction**

Compared to petroleum and coal, natural gas produces less carbon dioxide during combustion (Gustavsson and Sathre, 2006). Thus, in order to reduce emissions, natural gas accumulations became an even more important exploration target in the past decades. In addition to conventional gas, unconventional natural gas resources such as shale gas, gas hydrates, deep gas, gas in tight sandstones and coal-bed methane got more and more into the focus of research and exploration (Littke et al., 2011; Weniger et al., 2012; Ni et al., 2013; Ghazwani et al., 2018; Oshima et al., 2019; Qiao et al., 2020).

Microbial gas resources account for about 20% of the conventional natural gas reservoirs in the world (Rice and Claypool, 1981) and may dominate in some unconventional natural gas reservoirs, such as gas hydrate (Kvenvolden, 1988) and coal-bed methane (Aravena et al., 2003; Moore, 2012). Generally, microbial gas is considered as the product of anaerobic degradation of organic matter (OM) at low temperatures, and is typically trapped in relatively shallow and immature sediments (Rice and Claypool, 1981). However, the formation of microbial gas under geological settings is a complex

process, which is still poorly understood. One fundamental issue in this context is the characterization of microbial gas source rocks, which are essential for microbial gas exploration but are only rarely documented (Zhang et al., 2014).

The Qaidam Basin in China features the youngest and largest commercial Quaternary accumulation of microbial gas worldwide with a proven reserve of  $320 \times 10^9 \text{ m}^3$  (Pang et al., 2005; Dang et al., 2008). This accumulation is regarded as a typical early generation system due to the short depositional time and the young strata (Pang et al., 2005; Dang et al., 2008). Previous climatic studies of the Quaternary of the Qaidam Basin mainly concentrated on the pollen composition of sediments (Wang et al., 1999) and the stable isotopes of carbonate rocks (Rieser et al., 2009), indicating generally cold, extreme evaporative conditions in a closed lacustrine environment, which is further supported by widespread salt deposits (Lehmkuhl and Haselein, 2000). This setting is related to the rapid and significant uplift movement of the Tibetan Plateau (An et al., 2001) and the land-sea redistribution associated with the continental collision of India and Eurasia (Ramstein et al., 1997). Next to tectonic processes, climatic conditions can control erosional and depositional processes, and thus the sediment input into the basin. Deposition of OM-rich lacustrine mudstones - which act as the primary hydrocarbon source rocks in the basin - is closely related to paleoclimatic conditions (Huc, 1988; Jian et al., 2013).

OM is common in fine-grained sediments and derived from either aquatic sources (e.g. algae, cyanobacteria and macrophytic organisms) or terrestrial sources (higher land plants, bacteria) transported to the site of deposition. Abundance of the latter strongly depends on climate (with a humid climate being much more favorable than an arid one) and transport systems (with proximal deposits containing much more terrigenous OM than distal ones). Organic petrology can reveal the presence and size of higher land plant particles and aquatic OM, but not resolve microbes. Organic geochemistry, using the biomarker approach, can give information on the original type of fauna/flora present in the environment, as well as on depositional conditions, such as salinity or temperature (Peters et al., 2005). For these reasons, biomarkers are regularly used in paleoenvironmental studies (Böcker et al., 2013; Song et al., 2015b; Song et al., 2017; Qiao et al., 2021b).

This study focuses on the interpretation of elemental data on organic and inorganic carbon as well as total sulfur, organic geochemical and organic petrographic analysis of Pleistocene source rocks in the central Qaidam Basin. These Quaternary microbial gas source rocks have received little attention so far, and detailed information on OM quality and quantity, depositional environment, kerogen type and the related hydrocarbon generation potential are still missing. The quality and quantity of kerogen in the source rocks have been evaluated and the enrichment mechanism of OM as a basis for the exploration in the target area is discussed. In this context, also the terrestrial OM input needs to be considered. This study documents a case for such depositional settings and provides an example of an integrated approach using multiple proxies to analyze factors controlling OM accumulation in lacustrine environments.

### 4.3 Geological setting

Fig. 4.1. (a) Schematic map showing the location of the Qaidam Basin in China, (b) its geological setting and sample well locations, modified after Bao et al. (2017), and two transects (c and d, modified after Zhang et al., 2013a and Qiu et al., 2003). The dashed line with an arrow illustrates the depocenter shift during the depositional history of the basin.

Note: the different well symbols correspond to the different locations.

The Qaidam Basin is part of a basin-range system that is located at the northern edge of the Tibetan Plateau covering an area of around 120,000 km<sup>2</sup>, with an altitude up to 2.7–3.5 km above sea level. The continental basin formed in the Mesozoic and contains an exceptionally thick Mesozoic-Cenozoic sedimentary succession of 3–16 km (Jian et al., 2013) deposited on the basement consisting of igneous and meta-morphic rocks (Pang et al., 2005). The basin is surrounded by three mountain ranges with altitudes ranging from 4 to over 5 km, which are the Eastern Kunlun Mountain in the south, the Qilian Mountain in the east, and the Altyn Tagh Range in the northwest (Fig. 4.1a). The boundaries of the basin are represented by large-scale faults creating a high relief towards these surrounding mountain ranges (Fang et al., 2007).

Tapponnier et al. (2001) considered that the formation of the Qaidam Basin is the result of the convergent system in the northeastern Tibetan Plateau. The basin's Mesozoic tectonic settings are affected by the evolution of the Neo-Tethys, Meso-Tethys and the Mongol-Okhotsk Ocean and the collisions of related blocks (Gehrels et al., 2011). In the Cenozoic, the tectonic evolution is related to the India-Eurasia collision as well as to rise, shortening, thickening, and lateral extrusion of the Tibetan Plateau (Harrison et al., 1992; Tapponnier et al., 2001; Royden et al., 2008). In summary, the evolution of the basin took place during three tectonic-sedimentary stages: (1) piedmont fault depression stage in the Mesozoic; (2) unified depression stage from the Palaeogene to Neogene; and (3) subsiding depression in the east and cyclic folding in the center and west during the Quaternary (Dang et al., 2008).

Structurally, the western and southern parts are two Cenozoic depressions, and the northern part of the basin is a Mesozoic fault-block belt (Pang et al., 2005). During the Jurassic, the depocentres of the basin were located in the northern basin and they shifted to the western area during the deposition of the Palaeogene and Neogene. The depocentres were eastward-moving during the Pleistocene due to the collision with the Indian plate at the end of Neogene (the late Himalayan orogeny) (Pang et al., 2005). Based on the basement structure and the sedimentary sequence, the Qaidam Basin can be divided into four first-order structural units (Fig. 4.1b), which are the north and west Qaidam Uplifts, the Yiliping Depression, and the Sanhu Depression (Bao et al., 2017). Further, eleven second-order structural units can be distinguished, which are Sai-Kun Fault Sag, North Kunlun Fault Terrace, Mangya Sag, Dafengshan Bulge, South Slope, Sanhu Sag, North Slope, Mahai Salient, Delingha Fault Sag, Yuqia-Hongshan Fault Sag, and Gasi Fault Sag (Bao et al., 2017).

During the early Pleistocene, fluvial-deltaic sediments were deposited with abundant terrestrial debris. Afterwards, the lake basin reached its climax, with the deposition of dominantly deep-water fine-grained argillaceous sediments in the middle Pleistocene. Finally, the central area of the basin was continuously elevated due to the influence of the tectonic movement during the late Pleistocene (Dang et al., 2008). Quaternary sediments referred as the Qigequan Formation (Q<sub>1+2</sub>) mostly range from 1.5 to 2.5 km thick (1.7 km on average, greatest thickness about 3.4 km), with an average sedimentation rate of about 0.65 to 0.8 km/Ma. They were mainly deposited in the Sanhu Depression due to uplift in the

west and a consequent eastward shift of the depocenter (Fig. 4.1c and d; Dang et al., 2008; Shuai et al., 2013; Zhang et al., 2013a).

Fig. 4.2. Generalized Pleistocene stratigraphic column for the study area (modified after Jian et al., 2013; Zhang et al., 2013a).

The Q<sub>1+2</sub> Formation is divided into 12 intervals (K<sub>0</sub>–K<sub>13</sub>, from top to base) based on seismic reflectance features (Zhang et al., 2013a; Fig. 4.2). The middle Pleistocene (K<sub>6</sub>–K<sub>7</sub>) deposited at the most expansive stage of the Q<sub>1+2</sub> Formation corresponds to the Maximum Flooding Surface (MFS) of a long-term sequence cycle (Fig. 4.2). The lithology of Q<sub>1+2</sub> Formation is dominated by mudstones, silty mudstones, muddy lime-stones, and siltstones as well as some thin halite layers varying between 0.1 and 2.0 m thickness. Due to the influence of the tectonic movements in the late Pleistocene, around 0.5 km have been eroded along the Sebei- Tainan gas fields during the Holocene, while slightly less sediment eroded in the southern part of the Sanhu Depression (Zhang et al., 2013a).

The seven largest gas fields were all discovered in the central basin and are sourced from and trapped in Pleistocene, shallow, near-shore, lacustrine sediments (Fig. 4.1b; Shuai et al., 2013; Zhang et al., 2013a; Wang et al., 2015). All these gas fields comprise mainly natural gas produced by microbes in reducing, calcareous environments (Whiticar, 1999).

## 4.4 Samples and Methods

Seventy-three samples of Pleistocene source rocks were collected from seven wells and 30 samples were selected to be studied in detail, covering nine different stratigraphic intervals (Fig. 4.2). In accordance with observations by Zhang et al. (2014), two main types of source rocks are distinguished in the study area based on TOC (total organic carbon) and TS (total sulfur) contents as well as lithology.

The first type, here defined as organic facies A, comprises samples with high TOC and TS contents that are characterized by coarse grain size, poor gradation, with relatively high quartz and feldspar, but low clay mineral contents. Organic facies A samples are interpreted as a lacustrine-marginal facies, such as shallow water fluvio-lacustrine facies (Zhang et al., 2014).

The second type, here defined as organic facies B, comprises samples with low TOC and TS contents which are commonly characterized by fine grain size, good gradation, with relatively low quartz and feldspar, but high clay mineral contents and about 10–22% of authigenic minerals. Organic facies B samples are interpreted as lacustrine facies (Zhang et al., 2014).

The obtained samples were cut from cores and polished sections were made with a size of around 3–5 cm<sup>2</sup>. For the geochemical analysis, samples were pulverized using a disc mill.

In order to evaluate porosity and density, two samples from each organic facies were selected to prepare cuboid pieces of known volume.

Facies A and B accounts for approximately 20 and 70% of the whole Pleistocene interval, respectively, while the remaining 10% comprise siltstones, which have not been sampled (Fig. 4.2). Due to the high concentration of OM, all organic facies A samples, but only part of the organic facies B samples containing much less OM were studied in detail.

### 4.4.1 Elemental analysis

TOC and total inorganic carbon (TIC) contents were determined using a Liqui TOC II analyzer (Elementar Analysen System GmbH, Germany) while TS content was measured using a Leco S 200 sulfur analyzer. Details on the sample preparation, amount of samples, precision and analytical procedure are provided in Qiao et al. (2020). In addition to TOC, TIC, TS, the Fe content was determined using an ARL Perform' X 4200 wavelength-dispersive X-ray fluorescence (WD-XRF) spectrometer.

### 4.4.2 Rock-Eval pyrolysis

Rock-Eval pyrolysis was performed on a Rock-Eval VI instrument (Vinci Technologies) following the standard bulk rock method described by Behar et al. (2001). In an inert nitrogen atmosphere, the pyrolysis temperature was set to 300 °C and held for 3 min to release the S<sub>1</sub> (volatile hydrocarbon content, mg HC/g rock) fraction. Then the oven was heated to 650 °C at 25°/min to measure the S<sub>2</sub> (remaining hydrocarbon generative potential, mg HC/g rock) fraction. Before the first sample and after each four samples, standards and blanks were measured.

#### 4.4.3 Organic petrography

The preparation of the polished sections was based on the procedures described in detail by Zieger and Littke (2019). For reflectance measurements and maceral investigation a Zeiss Axio Imager microscope was used. A mineral standard of known reflectance (LEUKO-SAPHIR, 0.592%) was used for calibration before reflectance was measured at 546 nm in oil immersion. Strictly speaking, the maceral group “vitrinite” occurs only from the bituminous coal stage onwards, because the glasslike appearance (vitros (Greek) means glass) is not present at lower maturities. Thus, the term huminite is applied by coal petrologists. However, in geology and the petroleum industry, where vitrinite reflectance is commonly used, the term huminite is hardly known. Thus, in order to avoid confusion, the term huminite is used here when talking about the maceral group and “huminite/vitrinite reflectance (VRr)” when talking about reflectance. On each sample, at least 100 measurements were randomly taken and the mean VRr was calculated using the DISKUS Fossil software (Technisches Büro Carl H. Hilgers). Observations on macerals were not only made in reflected white light but also in a fluorescence mode at 500 times magnification. Maceral identification and counting follows the international standard ICCP system 1994 (ICCP, 1998 and 2001; Pickel et al., 2017; see also Taylor et al., 1998a, 1998b). More detailed parameters and introduction of the instrument and the used software are described in Zieger and Littke (2019).

#### 4.4.4 Biomarkers analysis

##### 4.4.4.1 Extraction and fractionation

About 5 g of each powdered sample was extracted by accelerated solvent extraction (ASE) using a DIONEX ASE 150 instrument (ThermoFischer SCIENTIFIC) with about 10 mL of dichloromethane (DCM) at 100 °C and 10 bar for about 15 min. After extraction, the removal of water and elemental sulfur were achieved by adding anhydrous sodium sulfate and activated copper powder to the extracts.

The extracts were subsequently separated into three fractions via column chromatography using an activated micro column packed with silica gel, which was activated at 200 °C for 12 h prior to the extract separation. Eluents of different polarity were used for fractionation: 5 mL *n*-pentane for the aliphatic hydrocarbons, 5 mL *n*-pentane/DCM (2:3 V:V) for the aromatic hydrocarbons and 5 mL methanol for the NSO components.

##### 4.4.4.2 GC-FID and GC-MS

Aliphatic and aromatic hydrocarbon fractions were analyzed by gas chromatography-flame ionization (GC-FID) and gas chromatography–mass spectrometry (GC–MS).

The GC-FID analysis was performed using a Fisons Instruments GC 8000 series, equipped with a split/splitless injector and a flame ionization detector (FID), using a Zebron ZB-1 capillary column (30 m length, 0.25 mm i.d.) with a 0.25-mm coating. The carrier gas was hydrogen at a velocity of approx. 40 cm/s. GC–MS analyses were performed using a quadrupol mass spectrometer Trace MS (Thermoquest), coupled to a Mega Series HRGC 5160 gas chromatograph (Carlo Erba, IT) equipped with a Zebron ZB-5 fused silica column (30 m × 0.25 mm ID) with a 0.25-mm coating. The MS was

operated in electron ionization (EI+) mode with an ionization energy of 70 eV and a source temperature of 200 °C, scanning from 35 to 700 amu at 1 s/decade with an inter-scan time of 0.1 s. The mass spectrometer was operated at a source temperature of 200 °C. The carrier gas was helium at a velocity of 30 cm/s.

Chromatographic conditions of GC-FID were: 1 µL split injection at an initial oven temperature of 60 °C, then programmed to 310 °C at 5 °C/min, with a final hold at 310 °C for 20 min. For the GC–MS, full scan analysis was operated on all samples. The GC oven temperature started at 80 °C (isothermal time 3 min) with splitless time of 60 s, then heating to 320 °C with a rate of 3°/min, and finally keeping an isothermal time at 320 °C for 20 min. All biomarker ratios were calculated from peak areas of the specific ion chromatograms.

#### 4.4.5 Porosity and density

In this study, porosity ( $\Phi$ ) was determined on regularly shaped samples by combining grain densities from helium expansion (pycnometry) experiments and bulk densities measured on blocks gauged by high precision vernier calipers. Samples were first cut into regularly shaped blocks and dried in a vacuum oven at 105 °C for 48 h to remove moisture and other sorbed fluids. Then, grain densities were measured on a self-customized He-Pycnometer. Details on the experimental set-up, procedure and evaluation are presented in Ghanizadeh et al. (2014). The bulk densities were determined by the ratio of dry sample weights  $m_d$  (g) and the bulk volumes  $m_v$  (cm<sup>3</sup>).

### 4.5 Results

#### 4.5.1 Elemental composition

Organic facies A samples have high TOC contents of 4.1–25.3 wt% and high TS contents of 1.5–3.7 wt% while organic facies B samples are characterized by lower TOC contents of 0.5–1.1 wt% and TS contents of 0.14–1.0 wt% (Table 4.1). Average TIC contents are lower in organic facies A than in organic facies B samples (Table 4.1). The Fe<sub>2</sub>O<sub>3</sub> of the samples are 2.6–5.2 wt% with an average value of 3.9 wt% (Table 4.1).

#### 4.5.2 Rock-Eval pyrolysis

Both S<sub>1</sub> and S<sub>2</sub> values in organic facies A samples (0.24–4.4 and 6.2–74.4 mg HC/g rock) are higher than those in organic facies B samples (0.08–0.81 and 0.56–3.1 mg HC/g rock). By contrast, both average Hydrogen Index (HI) and Tmax (temperature of maximum pyrolysis yield, °C) values are similar for the two organic facies with HI values varying between 56 and 493 mg HC/g TOC (200 mg HC/g TOC on average) and Tmax values ranging between 341 and 440 °C (411 °C on average). The results of Rock-Eval pyrolysis are shown in Table 4.1.

*Table 4.1. Total organic (TOC) and inorganic carbon (TIC), total sulfur (TS), and Rock-Eval data with free hydrocarbons ( $S_1$ ), hydrocarbon generation potential ( $S_2$ ), temperature of the highest pyrolysis yield ( $T_{max}$ ) and Hydrogen Index (HI).*

Well	Interval	Sample ID	Depth (m)	Organic Facies	TOC (wt.%)	TIC (wt.%)	TS (wt.%)	Fe (wt.%)	$S_1$ (mg HC/g rock)	$S_2$ (mg HC/g rock)	$T_{max}$ (°C)	HI (mg HC/g TOC)

HI = hydrogen index ( $S_2 \times 100/\text{TOC}$ ), mg HC/g TOC.

#### 4.5.3 Organic petrography

There are numerous autochthonous huminite particles, which can be used to measure  $VR_r$ . The  $VR_r$  values vary from 0.25 to 0.43% with an average value of 0.35% (Table 4.2). The volumetric percentage of OM observed is higher in organic facies A sample sections ranging from 5.9 vol% (18–868) to 38.9 vol% (18–861) (Fig. 4.3a–f) and lower in organic facies B sample sections ranging from 1.2 vol% (18–872) to 2.0 vol% (18–901) (Fig. 4.3g–i). Huminite is especially enriched in sample 18–861 (34.2 vol% of the whole rock counted; Table 4.2). Huminite particles are abundant in all the samples analyzed, representing 70 to 92 vol% of the total macerals counted. There are two kinds of huminite in organic facies A samples, i) massive, homogeneous huminite (Fig. 4.3a, b), and ii) huminite mixed with liptinite (Fig. 4.3e, f). The higher plant contribution to OM is further documented by the occurrence of inertinite, either as small detrital particles or as large fusinite (Fig. 4.3c, d) in some samples, although its abundance is usually low (0.0–0.8 vol% of whole rock, Table 4.2). Liptinite mainly occurs as sporinite (yellowish fluorescence; Fig. 4.3e, f) or resinite and fluorinite (greenish-yellow fluorescence;

Fig. 4.3d, f) forming oval to round bodies within densinite (Fig. 4.3f) and fillings of the cell cavities of huminite or fusinite (Fig. 4.3d). In organic facies B samples, the huminite appears more broken (Fig. 4.3g) and inertinite is very rare. As liptinite, only planar lamalginites and liptodetrinite (Fig. 4.3h) with yellow fluorescence color are observed in organic facies B samples.

*Table 4.2. TOC content, random huminite reflectance ( $VR_r$ ) and maceral composition (percentages based on whole rock samples).*

Pyrite is abundant in most organic facies A samples but rare in organic facies B samples, which is consistent with the TS concentration in both organic facies. It occurs either as euhedral crystals (Fig. 4.3a, c, e, g) or as assemblages of recrystallized framboidal pyrites (Fig. 4.3a, g) inserted in huminite or finely dispersed within the mineral matrix.

Fig. 4.3. Microphotographs showing macerals in the Pleistocene source rocks under incident reflected white light (left columns) and in fluorescence mode (right columns). a-d: sample 18-964, e-f: sample 18-861, and g-h: sample 18-894. All photomicrographs are at the same scale; the horizontal length is around 300 µm. Huminite-vitrinite, Fu-fusinite, Fl- fluorinite, S-sporinite, R-resinite, L-lamalginite/liptodetrinite, P-pyrite, I-inertinite.

#### 4.5.4 Biomarkers analysis

##### 4.5.4.1 *n*-Alkanes, acyclic isoprenoids and bicyclic alkanes

Fig. 4.4. (a, b) Gas chromatograms, (c, d) mass chromatograms of  $m/z$  191 of the aliphatic fraction showing the distribution of terpanes, and (e, f) mass chromatograms of  $m/z$  217 showing the distribution of steranes. See Appendix (Table A4.1) for detailed peak identification.

Figures on the left (a, c, e) represent sample 18-869 (organic facies A), those on the right sample 18-916 (organic facies B).

Acyclic alkanes range from  $n$ -C<sub>10</sub> to  $n$ -C<sub>40</sub> showing a bimodal distribution with maximum concentrations at  $n$ -C<sub>16</sub>,  $n$ -i-C<sub>17</sub> or  $n$ -C<sub>18</sub> for the short-chain homologs ( $< n$ -C<sub>21</sub>) and between  $n$ -C<sub>25</sub> to  $n$ -C<sub>27</sub> for the longchain homologs ( $> n$ -C<sub>25</sub>) in most samples (Fig. 4.4a and b). Organic facies A samples contain a clear odd  $n$ -alkane preference with the carbon preference index (CPI; Bray and Evans, 1961) greater than 2.1, while this preference is not obvious in the organic facies B samples (Fig. 4.4a and b; Table 4.3). Besides, some OM source indicators show a large difference between these two organic facies. TAR (terrigenous/aquatic ratio, Bourbonniere and Meyers, 1996) is higher in the TOC-rich

samples, while  $n\text{-C}_{17}/(n\text{-C}_{23} + n\text{-C}_{25} + n\text{-C}_{27})$  and Paq ratios (Ficken et al., 2000) are higher in the samples with low TOC contents (Fig. 4.4a and b; Table 4.3).

*Table 4.3. Ratios calculated from distributions of  $n$ -alkanes and acyclic isoprenoids.*

	K 13	18-900	B	0.64	0.48	1.35	1.18	0.62	1.03	0.32	3.25
		18-904	B	0.52	0.73	1.33	1.63	0.54	0.27	1.67	6.61
T 3	K 6	18-916	B	0.72	0.75	1.42	1.13	0.64	1.02	0.35	3.56

Pr = pristane; Ph = phytane;  $\text{CPI} = 2 \times \sum \text{odd } n\text{-C}_{23-29} / (\sum \text{even } n\text{-C}_{22-28} + \sum \text{even } n\text{-C}_{24-30})$ ;  $\text{TAR} = (n\text{-C}_{27} + n\text{-C}_{29} + n\text{-C}_{31}) / (n\text{-C}_{15} + n\text{-C}_{17} + n\text{-C}_{19})$ ;  $\text{Paq} = (n\text{-C}_{23} + n\text{-C}_{25}) / (n\text{-C}_{23} + n\text{-C}_{25} + n\text{-C}_{29} + n\text{-C}_{31})$ ;  $\text{HD/D} = 8\beta\text{-(H)-homodrimane}/8\beta\text{-(H)-drimane}$ .

Pristane (Pr) and phytane (Ph) are the dominating acyclic isoprenoids with the ratio of Pr/Ph ranging from 0.55 to 1.79 (Table 4.3). The ratio of their concentrations to those of their adjacent  $n$ -alkanes (Pr/ $n\text{-C}_{17}$  and Ph/ $n\text{-C}_{18}$ ) are 0.53–8.71 and 0.55–14.11, respectively. Unresolved complex mixture (UCM; Blumer et al., 1973) concentrations can be observed in all samples (Fig. 4.4a, b), which are sometimes the result of the biodegradation of saturated hydrocarbons (Formolo et al., 2008); however little is known about the chemical composition and origin of UCM (Hedges et al., 2000).

The bicyclic alkanes comprising  $8\beta\text{-(H)-drimane}$  (D) and  $8\beta\text{-(H)-homodrimane}$  (HD) are identified in the  $m/z$  123 mass chromatogram with ratios of HD/D of 1.34–8.15.

#### 4.5.4.2 Terpanes

Tricyclic terpanes ranging from  $\text{C}_{19}$  to  $\text{C}_{29}$  are identified in all samples. Increasing concentrations can be observed from  $\text{C}_{19}$  to  $\text{C}_{21}$  tricyclic terpanes, while decreasing concentrations occur from  $\text{C}_{23}$  to  $\text{C}_{25}$  tricyclic terpanes. Besides,  $\text{C}_{22}$  tricyclic terpane contents are similar to  $\text{C}_{19}$  and  $\text{C}_{25}$  tricyclic terpanes contents. Ratios of  $\text{C}_{24}$  tetracyclic/ $\text{C}_{23}$  tricyclic terpane range from 0.14–0.31 (Table 4.4).

Table 4.4. Biomarker parameters in the aliphatic fraction.

Sterane/hopanes = C<sub>27-29</sub> regular steranes/C<sub>29-35</sub> 17α-hopanes.

A series of hopanes, ranging from C<sub>27</sub> to C<sub>35</sub> except for C<sub>28</sub>, was observed in the studied samples and includes multiple stereoisomers (Fig. 4.4c, d). The distribution of hopanes varies in the different organic facies. For organic facies A, the identified hopanes include C<sub>27</sub>-C<sub>31</sub>  $\beta\beta$  (even to C<sub>32</sub>  $\beta\beta$  in some samples), C<sub>29</sub>-C<sub>30</sub>  $\beta\alpha$ , and C<sub>27</sub>-C<sub>32</sub>  $\alpha\beta$  with C<sub>29</sub>  $\beta\beta$  being the dominant compound. Besides, C<sub>27</sub>-17 $\beta$ (H)-22,29,30-trisnorhopane (C<sub>27</sub> $\beta$ ) and hopenes including C<sub>29</sub>-C<sub>30</sub> neohop-13(18)-enes, and C<sub>30</sub> hop-17(21)-ene are observed. C<sub>29</sub>N (25-Norhopane) is present in all samples, although with different concentrations (Fig. 4.4) with C<sub>29</sub>N/C<sub>30</sub>H ratios clearly higher in facies B (avg. 0.29) than in facies A (avg. 0.05) (Table 4.4). Moreover, no other compounds such as gammacerane or C<sub>33</sub>, C<sub>34</sub> or C<sub>35</sub> homohopanes have been found in significant abundance. In organic facies B samples, gammacerane occurs and C<sub>32</sub>-C<sub>35</sub>  $\alpha\beta$  homohopanes are more abundant, while hopenes and  $\beta\beta$  hopanes are missing.

#### 4.5.4.3 Steroids

Steranes and diasteranes were observed by monitoring the *m/z* 217 ion (Fig. 4.4e, f). In organic facies A, steranes are dominated by the C<sub>29</sub>  $\alpha\alpha\alpha$ 20R-sterane, followed by C<sub>29</sub>  $\alpha\beta\beta$ -sterane which co-elutes with  $\beta\beta\beta$ (R)-sterane (Fig. 4.4e and f). Additionally, pregnane and homopregnane were also detected in low abundances. However, high contents of pregnane and homopregnane can be observed in organic facies B samples (Fig. 4.4f). In these samples, besides the contents of the C<sub>27</sub>-C<sub>29</sub>  $\alpha\alpha\alpha$ 20R-steranes, the contents of other steranes and diasteranes are high as well (Table 4.4).

#### 4.5.4.4 Aromatic hydrocarbons

The distribution of aromatic hydrocarbons concerned is shown in Fig. 4.5 (a and b). Unlike aliphatic hydrocarbons, parameters based on aromatic hydrocarbons show little differences between the two organic facies. This is expected due to the low to marginal maturity of studied samples. The most abundant peak is phenanthrene (P; *m/z* 178) followed by dibenzofuran (DBF; *m/z* 168), methylphenanthrenes (MPs; *m/z* 192) and ethylphenanthrenes + dimethylphenanthrenes (EPs + DMPs; 206). Among DMPs, 1,3- + 3,9- + 2,10- + 3,10-DMP is the most abundant peak with 1,7-DMP/(1,3- + 3,9- + 2,10- + 3,10-DMP) ratios of 0.36–0.55 in most samples except for sample 18–878 (Table 4.5). Further, a positive relationship between 1,7-DMP/(1,3- + 3,9- + 2,10- + 3,10-DMP) and 1-MP/9-MP ratios (0.60–1.73, 0.87 on average) can be observed. Trimethylnaphthalenes (TMNs; *m/z* 170), tetramethylnaphthalenes + dibenzothiophene (TeMNs + DBT; *m/z* 184), and fluorene (FL; *m/z* 166) show small abundances compared to above compounds. DBT, a compound containing sulfur, shows relatively low contents in the normalized distribution of FL, DBF and DBT (Fig. 4.6a) and compared to P (Fig. 4.6b). Among TMNs, the 1,3,6-TMN is the most abundant compound with 1,2,5-TMN/1,3,6-TMN ratios of 0.27–0.82 and 1,2,7-TMN showing small concentrations with 1,2,7-TMN/1,3,7-TMN ratios of 0.49–1.73. Other aromatic hydrocarbons with biological origin such as of cadalene (Cad; *m/z* 183) and diterpenoids including retene (Ret; *m/z* 219), 19- + 18-norabieta-8,11,13-trienes (*m/z* 241), tetrahydroretene (Tet; *m/z* 223), dehydroabietane (Deh; *m/z* 255), simonellite (Sim; *m/z* 237) and 9- + 2-methylretenes (Mrets; *m/z* 233) occur in small concentrations (Fig. 4.5).

TMN: trimethylnaphthalene; MP: methylphenanthrene; DMP: dimethylphenanthrene; DBT: dibenzothiophene; P: phenanthrene; FL: fluorene; DBF: dibenzofuran.

#### 4.5.5 Porosity and density

The mean wet bulk density (WBD) value is 2.10 g/cm<sup>3</sup> for organic facies A samples and 2.22 g/cm<sup>3</sup> for organic facies B samples. The mean porosities (Po) are 39.59% and 37.28% for organic facies A and B samples, respectively.

### 4.6 Discussion

#### 4.6.1 Thermal maturity of organic matter

Both the T<sub>max</sub> and VR<sub>r</sub> values illustrate that the source rocks are thermally immature with average values of 411 °C and 0.33%, respectively. This is consistent with the following molecular parameters.

In organic facies A samples, the high abundances of C<sub>27</sub>β, 17β(H),21β(H)-hopanes, neohop-13(18)-enes and C<sub>30</sub> hop-17(21)-ene (Mackenzie et al., 1980; ten Haven et al., 1986; Sinninghe Damsté et al., 2014; Volkman et al., 2015) indicate an immature stage. The low abundances of these compounds in organic facies B suggest a different source material rather than a different maturity compared to organic facies A. The same conclusion can be deduced from other parameters based on steranes and

hopanes including the  $C_{29}$   $\alpha\alpha\alpha$  20S/(20S + 20R) ratios and  $C_{29}$  vs.  $C_{30}$   $\alpha\beta/(\alpha\beta + \beta\alpha + \beta\beta)$  ratios (Fig. 4.7). It is thus clear that the studied samples are immature.

Fig. 4.7.  $C_{30}$   $\alpha\beta/(\alpha\beta + \beta\alpha + \beta\beta)$  vs.  $C_{29}$   $\alpha\beta/(\alpha\beta + \beta\alpha + \beta\beta)$  hopanes diagram, indicating maturity. Note: symbols represent sample locations (see Fig. 4.1b).

#### 4.6.2 Origin of organic matter

The majority of the analyzed samples comprise gas prone mixed type II-III kerogen (Fig. 4.8a, Pepper and Corvi, 1995). Here, there is no clear distinction between these two organic facies samples. Actually, the kerogen type of organic facies B cannot be determined accurately based on Rock-Eval data (Fig. 4.8a), since samples with low TOC contents are affected by the mineral matrix effect (MME) in laboratory pyrolysis (Katz, 1983; Espitalié et al., 1985; Grohmann et al., 2019; Beti et al., 2021), i.e. this effect dramatically lowers the true  $S_2$  and thus HI value of samples with TOC contents <3 wt%. As a result, the low  $S_2$  values of organic facies B samples are partly due to the MME; i.e. the type III kerogen character is not due to abundant higher plants OM in these samples as also proven by microscopy investigations. Microscopic observation shows that the OM in organic facies A samples is mainly composed of large fragments (from about 1 to >200  $\mu\text{m}$ ) of fusinite and huminite as well as sporinite and resinite/fluorinite (Fig. 4.3a-f) with little algae-derived OM. However, smaller huminite particles and algaederived OM such as thin lamalginite and liptodetrinite are commonly observed in organic facies B samples. There is a very good positive relationship between volumetric percentages of OM and TOC contents ( $R^2 = 0.97$ ) for organic facies A samples (Fig. 4.8b) indicating that most of the organic material is visible in the form of macerals derived from higher plants. This is in agreement with the Rock-Eval results showing type II-III kerogen (Fig. 4.8a). For organic facies B samples, the relationship between TOC and volume percentage of macerals is less clear with a correlation coefficient of only 0.2 implying that part of the OM is submicroscopic, which is consistent with the presence of very small liptodetrinite and very thin lamalginite (Fig. 4.3h). This observation might indicate a pronounced microbial input. This mixed OM is thus interpreted to originate from microbes and higher plants.

This pyrolytic and microscopic information is further supported by molecular geochemical data. Abundant OM input is proposed to originate from plants living close to or in the water.  $\text{Paq} > 0.4$

indicates a major input of submerged/floating species (Ficken et al., 2000; He et al., 2020) for organic facies A samples, which probably grew in freshwater environments at the lake margin, close to land. This marginal environment is also indicated by the petrographic data (large huminite and fusinite fragments) as well as by the abundant odd-numbered long-chain *n*-alkanes (e.g. *n*-C<sub>27</sub>; Fig. 4.4a). Abundant middle-chain odd-numbered nalkanes correspond not only to *Sphagnum* mosses (Nichols et al., 2006; Bingham et al., 2010), *Chara* (Mead et al., 2005) and freshwater algae (Riboulleau et al., 2007), but also aquatic angiosperms, such as freshwater *Nymphaea* (Coetzee, 1967) and *Ruppia* (Mead et al., 2005; He et al., 2020). The odd-numbered long-chain *n*-alkanes leading to high CPI values (up to 4.7) might indicate higher land plants. They would also be in accordance with the occurrence of *Botryococcus braunii*, race A (Derenne et al., 1997), although these algae were not detected microscopically. Moreover, the higher concentration of hop-17(21)-enes might represent several eukaryotic phyta (e.g., ferns, mosses, lichens, fungi) (Bottari et al., 1972; Wakeham, 1990; Bechtel et al., 2007) in organic facies A. The interpretation of such an assemblage of OM goes along with the mixed occurrence of huminite, sporinite, fluorinite, and fusinite (Fig. 4.3a-f).

Fig. 4.8. (a) Plots of total organic carbon (TOC) vs.  $S_2$  indicating kerogen types and (b) TOC vs. volumetric percentage of OM indicating that most OM is well visible as macerals (see Fig. 4.3). Note: symbols represent sample locations (see Fig. 4.1b).

By contrast, algae/phytoplankton or cyanobacteria contribute much more to the total OM in organic facies B samples. On a molecular level, this is confirmed by a higher concentration of *n*-C<sub>17</sub> (mainly derived from stearic acid in algae; Riboulleau et al., 2007) compared to concentrations of *n*-C<sub>23</sub>, *n*-C<sub>25</sub> and *n*-C<sub>27</sub> alkanes (Table 4.3). This observation is consistent with the presences of planar lamalginite and liptodetrinite (Fig. 4.3h). The occurrence of monomethylalkanes (MMAs), having a methyl group at position 4, 5, 6 or 7 (Fig. 4.4a and b) indicates the input from cyanobacteria living in

microbial mats found in both salt and freshwater environments (Kenig, 2000; Bauersachs et al., 2009; Pawlowska et al., 2013); these compounds are present in both organic facies.

Terrestrial plant input is probably not derived mainly from trees/shrubs/ferns and mangroves, as they typically produce very low Paq values of  $<0.3$  (Ficken et al., 2000; Mead et al., 2005; He et al., 2020) and a distribution of long chain *n*-alkanes maximizing at  $C_{29}$ ,  $C_{31}$  or  $C_{33}$  (Mead et al., 2005; Volkman et al., 2015; He et al., 2020); such a pattern is not observed in the studied samples. The absences of diploptene and ferenes argue also for the lack of ferns (Bottari et al., 1972). This conclusion is further supported by the relatively low  $C_{24}$  tetracyclic terpane/ $C_{23}$  tricyclic terpane (0.05–0.33) and  $C_{19}/(C_{19} + C_{23})$  tricyclic terpane (0.09–0.36) ratios (Table 4.4) (Peters and Moldowan, 1993; Peters et al., 2005; Volk et al., 2005; Volkman et al., 2015) as well as low 1-MP abundances (Alexander et al., 1988). The low oleanane abundance indicates a minor contribution from angiosperms (Moldowan et al., 1994) (Fig. 4.4c and d). It should be noted that this interpretation is not inconsistent with the high content of  $C_{29}$  steranes in organic facies A samples (Fig. 4.4e) as these compounds are not only associated with terrestrial higher plants (Volkman, 2003) but can be evolved from some aquatic plants and algae enrich in  $C_{29}$   $\beta$ 2 sitosterol and  $C_{29}$  stigmasterol (Huang and Meinschein, 1979; Moldowan et al., 1986; Volkman, 2003; Volkman et al., 2015).

1,2,7-TMN used as a marker of angiosperm input (Peters et al., 2005) and 1,2,5-TMN associated with both conifers (Alexander et al., 1988) and angiosperms (Strachan et al., 1988) are present, but seemingly lower in concentration compared to Upper Cretaceous source rocks from e.g. the Gippsland Basin, Australia where both angiosperms and gymnosperms are important precursors of the OM (Jiang and George, 2019). Retene and 1,7-DMP related to conifers (Strachan et al., 1988; van Aarssen et al., 2000) and other aromatic conifer biomarkers including Cad, Sim, 19- + 18-nor-abieta-8,11,13-triene, Tet, Deh and 9- + 2-Mrets (see Fig. 4.5; Simoneit, 1977; Bastow et al., 2001; Otto and Wilde, 2001; Haberer et al., 2006) are present, but in small concentrations, whereas aromatic triterpenoids related to angiosperms (Haberer et al., 2006; Nakamura et al., 2010) are only present at the detection limit.

In summary, there is a much higher contribution of odd-numbered long-chain *n*-alkanes (peaking at *n*- $C_{27}$ ) and of higher plants-derived macerals in organic facies A than in organic facies B samples, indicating major input of higher plants OM or macrophytes. However, this material does not seem to be mainly derived from gymnosperm or angiosperm wood. This is consistent with a pollen study indicating the abrupt disappearance of some subtropical and coniferous trees coinciding with a dramatic expansion of drought-tolerant herbaceous plants (e.g. Ephedra, Artemisia, and Chenopodiaceae) and the expansion of the steppe during 2.6–1.83 Ma (Wu et al., 2011).

A microbial contribution was interpreted for both organic facies evidenced by the occurrence of hopanoids, branched alkanes (Shiea et al., 1990) and bicyclic alkanes (Alexander et al., 1983; Alexander et al., 1984) (Fig. 4.4a-b). Furthermore, neohop-13(18)-enes (Fig. 4.4c and d) as well as 1,3,6,7-TeMN (Fig. 4.5), which are typical biomarkers associated to a microbial source of OM (Jiang et al., 1998; Cesar and Grice, 2017; Volkman et al., 2015) were observed in both organic facies. Based on the

steranes/hopanoids ratios, which range from 0.21 to 3.29 (avg. 1.48) and 0.58 to 1.77 (avg. 0.99) in organic facies A and B samples, respectively (Table 4.4), a strong microbial contribution is present, which is slightly more pronounced in organic facies B as compared to organic facies A. Steranes originate mainly from eukaryotic OM (algae and higher plants) (Peters et al., 2005), while hopanoids (e.g. hopanes and hopenes) are generally regarded as biomarkers for aerobic bacteria (Innes et al., 1997), although biohopanoids were identified as well in sulfate-reducing bacteria under strictly anoxic conditions (Blumenberg et al., 2006).

Briefly, OM of organic facies A is dominated by aquatic higher plants, i.e. large plants growing at the margin of the lake and submerged angiosperms, while organic facies B is dominated by saltwater algae. Cyanobacteria made a certain contribution to the kerogen in both organic facies, whereas terrestrial higher land plants account for only a small proportion of the OM. Other microbial contribution is on average slightly more pronounced for organic facies B than organic facies A.

#### 4.6.3 Depositional setting

Changes in water levels in lakes as well as growth rates of plants in the adjacent drainage areas can be triggered by climatic changes (Carroll and Bohacs, 1999; Renaut et al., 2013), which then can affect the paleosalinity and biotic components (Qiao et al., 2021b). During arid periods, water salinity tends to be increased, terrestrial input decreased and a stratified water column may develop. On the contrary, higher precipitation increases the amount of terrestrial OM, sediment and nutrient input into the lake.

##### 4.6.3.1 Paleosalinity

Salinity plays an important role in aquatic organism community composition in lake systems (Romero-Viana et al., 2012). The TOC/TS ratios (Fig. 4.9a; Berner and Raiswell, 1984) indicate that organic facies A samples were deposited in a shallow freshwater environment without stratification, which is consistent with the low abundance of  $C_{33}$ ,  $C_{34}$  and  $C_{35}$  homohopanes (Sinninghe Damsté et al., 1995b; Peters et al., 2005). Besides, the high concentration of  $C_{23}$ – $C_{31}$  odd *n*-alkanes is an indication of low salinity during deposition of organic facies A (Fig. 4.4a, Riboulleau et al., 2007). In contrast, organic facies B samples developed in hypersaline depositional environments and partly even in lakes with water column stratification, which is supported by the high pregnane and homopregnane compared to steranes (ten Haven et al., 1985; Requejo et al., 1997), high tricyclic terpanes/ $C_{30}$   $\alpha\beta$  hopane ratios (Kruge et al., 1990; Peters et al., 2005) (Fig. 4.9b), and no carbon-number preference among the *n*- $C_{24}$ –*n*- $C_{35}$  alkanes (Peters et al., 2005; Fig. 4.4b). Such a hypersaline environment is further supported by high gammacerane/ $C_{30}$   $\alpha\beta$  hopane and homodrimane/drimane (HD/D) ratios as abundant homodrimane is characteristic for calcareous mudstones and probably highly saline conditions, while drimane is usually enriched in most crude oils from the freshwater environments (Fan et al., 1991; Al-Arouri et al., 1998) (Fig. 4.9c). Different paleosalinities during deposition of the two organic facies are also indicated by  $C_{22}/C_{21}$  tricyclic terpane ratios (Table 4.4; Peters et al., 2005). Under the influence of the Himalayan

orogeny of this period, the prolonged arid/frigid climatic conditions (Wang et al., 1999; Rieser et al., 2009; Zhang et al., 2013b; Zhuang et al., 2011; Cai et al., 2012) favor a hypersaline lake environment with the primary OM being derived from algal and microbial organisms (organic facies B samples) (Warren, 1986). However, from time to time, freshwater dominated the lakes, possibly due to either more humid time intervals or periods when more glacial meltwater was transported to the lakes. It is also possible that marginal parts of the lakes were more freshwater dominated, due to inflow of rivers, whereas central parts were more saline and possibly stratified. For example, it is known that *Botryococcus* blooms occur currently in the saline lakes of the arid Coorong region after heavy rain (Cane, 1976; Grice et al., 1998). Meanwhile, modern lakes in the Tibetan Plateau are common home to *Chara* and *Ruppia* (Liu et al., 2018). *Chara* live in the photic zone in freshwater environments (Liu et al., 2013) and would become extinct with rising salinity (Krull et al., 2009). Therefore, their presence in the organic facies A samples, as indicated by the GC–MS results and discussed above, supports the interpretation of a freshwater, lacustrine environment during the deposition of facies A. Organic facies B represents the central area of the lake system with higher salinity.

Fig. 4.9. (a) TS vs. TOC, (b) tricyclic terpanes/ $C_{30}$  hopane vs.  $C_{21}$ - $C_{22}$  steranes/ $C_{27}$ - $C_{29}$  steranes, and (c) homodrimane/drimane vs. gammacerane/ $C_{30}$  hopane. Note: symbols represent sample locations (see Fig. 4.1b).

#### 4.6.3.2 Paleoredox conditions

In addition to paleosalinity, paleoredox conditions can affect paleoproductivity and OM preservation. The relative concentrations of TOC, TS and iron indicate dysoxic to slightly anoxic bottom water conditions for organic facies A samples and oxic conditions for organic facies B samples (Fig. 4.10a), i.e. there is a major difference between organic facies A and B. The  $\text{Pr}/n\text{-C}_{17}$  vs.  $\text{Ph}/n\text{-C}_{18}$  diagram indicates reducing conditions both for organic facies A and B samples (Fig. 4.10b), with quite some variability for organic facies A. In shallow, hypersaline lakes (Blumenberg et al., 2015; Lee et al., 2019) microbial mats may develop that can provide a seal insulating the under-lying reductive sediments from the overlying oxidizing environment (Pawlowska et al., 2013). Thus, local reducing conditions formed in microenvironments around abundant OM can occur (i.e. “mat-seal effect”; Pawlowska et al., 2013). MMAs (having a methyl group in position 4–7) indicating the presence of microbial mats (Sinninghe Damsté et al., 1995a; Pawlowska et al., 2013) are abundant in the studied samples (Fig. 4.4a and b). Finally, the large sizes of framboidal pyrite in the mineral matrix of the organic facies B samples (Fig. 4.3h) might indicate that the redox interface was very close to the sediment/water interface and not in the water. However, it has to be noted that the amount of framboidal pyrite is rarely high enough to make statistics. Small, dot-like pyrites are abundant, whereas rather large framboidal pyrites can be observed in organic facies A samples as well (Fig. 4.3a, c and e). It should be noticed that dot-like pyrites are randomly distributed over the entire polished sections, but all large framboidal pyrites inserted in or next to OM.

Fig. 4.10. (a) Ternary diagram showing the relative concentration of TOC, TS and Fe. (b) Pristane/ $n\text{-C}_{17}$  vs. phytane/ $n\text{-C}_{18}$  reflecting kerogen type, maturity, and depositional environment. Note: symbols represent sample locations (see Fig. 4.1b).

In summary, lake water in marginal areas, where organic facies A was deposited, was less saline than in central areas, represented by organic facies B. Bottom waters were during most times oxygen-depleted but not completely anoxic.

#### 4.6.4 Accumulation rates and methanogenesis

The thermally immature to very early mature stage of the studied samples is a necessary prerequisite for intense microbial methane generation (Schoell, 1980). Both, organic facies A and facies B samples have the potential to generate microbial gas. Organic facies A is clearly more enriched in TOC, which is regarded favorable for microbial gas generation. On the other hand, the larger area of unresolved complex mixture (UCM; Fig. 4.4a and b) and rather high 25-norhopane to hopane ratios in organic facies B indicate that organic facies B samples already underwent slight microbial degradation (Blumer et al., 1973; Peters et al., 2005). This degradation of OM might also explain the abnormally high maturity inferred from biomarkers of organic facies B samples, i.e. steranes are commonly known to be degraded in the order  $\alpha\alpha\alpha$  20R and  $\alpha\beta\beta$  20R >  $\alpha\alpha\alpha$  20S and  $\alpha\beta\beta$  20S, while the 22S counterparts of the 17 $\alpha$ -homohopanes are more stable than their 22R counterparts (Volkman et al., 1983; Peters et al., 2005).

<sup>1</sup> Linear Sedimentation Rate; calculated as: LSR = Thickness/(Age top - Age bottom).

Previous isotopic data shows that most microbial gas in the study area is generated in bacterial carbonate reduction environments (Hu et al., 2010; Hu et al., 2015; Pang et al., 2005; Shuai et al., 2016; Zhang et al., 2003; Zhang et al., 2013a). Carbonate reduction as the main methanogenesis pathway in some non-marine freshwater settings has been observed before (Coleman et al., 1988; Schoell, 1988). Low DBT and TS contents in the samples (Fig. 4.6) suggest that microbial sulfate reduction did not contribute to OM degradation in the study area significantly. Thus, OM remained well-preserved before the stage of methanogenesis was reached. Generally, cold climatic conditions along with saline environments, as interpreted for the study area, are favorable for carbonate reducing methanogenesis at relatively great depths (Schoell, 1988; Whiticar, 1999; Whiticar, 2020). In this “cold” case, the range of microbial gas generation is shifted to greater depth, which is more favorable for preservation of generated gas than very shallow microbial gas generation. Furthermore, high sedimentation rates are

favorable for microbial gas generation which can be assumed for the Qaidam area. Generally, areas of high paleo bio-productivity do not necessarily coincide with areas of OM enrichment and preservation in sediments (Demailson and Moore, 1980). Within lacustrine systems, primary productivity of OM, redox conditions at the sediment water interface and sedimentation rates are regarded as primary controlling factors for accumulation and preservation of OM (Katz, 2001). Thus, the available data was used to calculate the accumulation rates of bulk sediment as well as organic carbon, carbonates, and clastic minerals based on linear sedimentation rates estimated from the ages and thickness of the different intervals (Fig. 4.2, Table 4.6, Stein, 1991). Calculated sedimentation rates range from 429 to 1107 m/Ma. There are some uncertainties concerning exact stratigraphic boundaries and ages and it is possible that short term non-deposition or erosion affected the area. Even if this effect is neglected, calculated sedimentation rates are high in the entire area, i.e. the organic biomass was rapidly buried, limiting aerobic microbial decay.

<sup>1</sup> Accumulation rate (AR); calculated as AR = Matter (i.e. TOC, Carbonate and Silicate in %) × SR × (WBD-1.025Po/100) (after Lückge et al., 1996)

In order to compare ancient sedimentary rocks and recent sediments, accumulation rates rather than sedimentation rates should be used, taking rock densities into account. Accordingly, dry bulk

densities (DBD) and porosities were measured (Table 4.7), in order to calculate WBD. In Table 4.7, accumulation rates are summarized for bulk sediment, TOC, carbonate.

The organic carbon mass accumulation rate of TOC was calculated based on the equation by Lückge et al. (1996):

$$\text{MAR}_{\text{TOC}} = \text{TOC}/100 \times \text{SR} \times (\text{WBD} - 1.025 \times \text{Po}/100) \quad (4.1)$$

where  $\text{MAR}_{\text{TOC}}$  is mass accumulation rate of TOC ( $\text{g C cm}^{-2}\text{a}^{-1}$ ), TOC represents total organic carbon (wt%), SR is mean sedimentation rate (cm/a), WBD is wet bulk density based on measured values of samples 18–858, 18–860, 18–867 and 18–915 ( $2.10 \text{ g/cm}^3$  and  $2.22 \text{ g/cm}^3$  for organic facies A and B samples, respectively), and Po represents porosity based on measured values presented above ( $39.59\%$  and  $37.28\%$  for organic facies A and B samples, respectively).

The Qigequan Formation was deposited under rather stable tectonic subsidence, although it was weakly uplifted in the latest Quaternary (Zhang et al., 2013a). The results suggest that the accumulation rates of TOC of both organic facies A samples ( $74.77\text{--}449.14 \text{ g C m}^{-2}\text{a}^{-1}$  with an average value of  $198.08 \text{ g C m}^{-2}\text{a}^{-1}$ ) and organic facies B samples ( $8.28\text{--}40.41 \text{ g C m}^{-2}\text{a}^{-1}$  with an average value of  $18.95 \text{ g C m}^{-2}\text{a}^{-1}$ ) are distinctly higher than e.g. in OM-rich Quaternary marine sediments sites drilled by ODP such as Baffin Bay, Labrador Sea ( $0.1\text{--}3 \text{ g C m}^{-2}\text{a}^{-1}$ ; Stein, 1991). Furthermore, they are greater or close to upwelling areas offshore Peru and Oman ( $0.4\text{--}15.9 \text{ g C m}^{-2}\text{a}^{-1}$  with an average value of  $3.69 \text{ g C m}^{-2}\text{a}^{-1}$ ; Lückge et al., 1996) and open-ocean gyres ( $0.026\text{--}378 \text{ g C m}^{-2}\text{a}^{-1}$  with an average value of  $55.85 \text{ g C m}^{-2}\text{a}^{-1}$ ; Suess, 1980), respectively. This is due to the tectonic setting leading to strong erosion in the hinterland and thus high sediment accumulation rates, combined with lake environments favorable for OM production and preservation. Compared to other lake systems, the values of organic facies B samples are slightly lower and those of facies A are slightly higher than those in Brazilian lakes, such as Feia ( $43 \text{ g C m}^{-2}\text{a}^{-1}$ ; lake altitude is 850 m) and Agua Preta de Baixo ( $22 \text{ g C m}^{-2}\text{a}^{-1}$ ; lake altitude is 240 m), where also large populations of floating macrophytes developed during the Holocene (Turcq et al., 2002). It should be noted that organic facies B is generally more prevalent than facies A in the analyzed Pleistocene sequence (about 70 and 20%, respectively) and further both facies are partly interlayered with each other. Since the above mentioned calculations are based on average values for each facies, there is a rather high uncertainty with respect to the absolute values. Nevertheless, even with a total average of about  $50.2 \text{ g C m}^{-2}\text{a}^{-1}$  (taking into account the respective percentage of each facies) there is no doubt about the very high organic carbon accumulation rates in this thick, Pleistocene interval leading to rapid burial of large amounts of kerogen into the zone of methanogenesis. Furthermore, sulphate availability is usually limited in freshwater environments. In case of the Qaidam lake, the marginal areas (organic facies A) were probably less saline than the more central areas represented by organic facies B. Therefore, OM in the freshwater environment (facies A) reached the zone of methanogenesis not only rapidly but also quite well preserved, whereas organic facies B was more degraded due to higher levels of bacterial sulphate reduction. Temperature critically determines the methanogenesis pathway, i.e., acetate fermentation mainly occurs in sediments at a shallower depth

in warm climates, while greater depth with cold climatic conditions is in favor of the carbonate reduction pathway (Schoell, 1988). Given the above, even though there are minor freshwater microenvironments in marginal lake areas (organic facies A), the cold and dry climate conditions with high burial rate are favorable for carbonate reduction in the Qaidam area. Carbonate reduction as the main methanogenesis pathway in some nonmarine lakewater settings has been observed before (Coleman et al., 1988; Schoell, 1988). Methanogenesis from organic facies A started at much shallower depth (due to limited sulphate availability) and much of this generated methane might have escaped to the surface.

Another area rich in commercial quantities of microbial gas is the southern foreland of the Alps, Italy (Mattavelli et al., 1983), where also rapid sedimentation in the course of mountain building and erosion took place during the Neogene, mainly in freshwater environments.

In summary, the high OM accumulation rate, OM -type and -preservation and its fast burial were the conditions leading to a high microbial gas potential of the Pleistocene lacustrine deposits in the central Qaidam Basin.

#### 4.7 Conclusions

This study combines elemental data including elemental total organic (TOC), inorganic carbon (TIC) and sulfur (TS), as well iron, Rock-Eval pyrolysis, biomarker analysis and microscopic investigation of Pleistocene, microbial gas source rocks in the central Qaidam Basin. The following conclusions concerning thermal maturity of organic matter (OM), its origin and preservation, as well as depositional environment together with paleoclimatic are drawn:

1) Sediments are generally rich in OM, but contain two vastly different organic facies (A and B), which are interlayered with each other. These two facies both represent lacustrine systems.

2) Periodically, shallow freshwater fluvio-lacustrine, environments similar to inundated swamps developed during high water levels at the lake margins with suboxic to anoxic redox conditions in bottom water favoring the development of OM-rich (4.1–25.3 wt% TOC) and sulfur-rich (1.5–3.7 wt% TS) sediments. They represent organic facies A, which, however, accounts for only a small proportion of the whole sedimentary sequence. More common is organic facies B, represented by samples with moderate contents of TOC (0.5–1.1 wt %) and TS (0.14–1.0 wt%), which were deposited under more oxic bottom waters in more distal parts of the lake. However, reducing conditions (indicated by biomarker data) were probably sometimes present in the sediment caused by the “mat-seal effect”.

3) The kerogen is classified as gas prone mixed type II-III in most samples, which are thermally immature. A large part of it is derived from aquatic higher plants in sediments representing organic facies A, i.e. macrophytes and submerged angiosperms, that were growing at the lake margin. By contrast, organic facies B samples mainly developed from saltwater algae. Cyanobacteria contributed to the kerogen in both organic facies, while other microbial contribution was more pronounced for

organic facies B than organic facies A. Terrestrial higher land plants only provided a minor part of the kerogen.

4) The calculated organic carbon accumulation rate of both organic facies A (74.77–449.14 g C m<sup>-2</sup>a<sup>-1</sup>) and organic facies B (8.28–40.41 g C m<sup>-2</sup>a<sup>-1</sup>) is very high favoring rapid burial of kerogen into the zone of methanogenesis. Furthermore, the cold climatic conditions shifted microbial gas generation to greater depths, where favorable temperatures are present. These factors as well as the low sulphate availability in freshwater, limiting microbial sulphate reduction coupled to OM oxidation, make this sequence an excellent microbial gas exploration and production target.

## **5 Climatic conditions during the Pleistocene in the Central Qaidam Basin, NE Tibetan Plateau: Evidence from GDGTs, stable isotopes and major and trace elements of the Qigequan Formation**

### **5.1 Abstract**

Sediments in the Tibetan Plateau (TP) region of NW China provide sensitive records of climate change and its impact on past ecosystems. The Qaidam Basin, located in the north-eastern part of the TP contains an exceptionally thick Meso-Cenozoic sedimentary succession; it is also the largest sedimentary basin in the TP. Here, new data on Pleistocene sediments on the TP are reported. Evidence from GDGTs, stable isotopes as well as major and trace elements of the Pleistocene Qigequan Formation was used to decipher depositional conditions within the water column and the origin of kerogen. This information was further applied to interpret factors controlling organic matter (OM) accumulation and climate conditions. In accordance with a previous study, the results show that two completely different organic facies are present, representing vastly different lake environments. OM of organic facies A samples is mainly derived from a mixture of C3 higher plants and phytoplankton, deposited in a shallow freshwater lake environment under dysoxic to anoxic bottom water conditions. In contrast, OM of organic facies B is mainly derived from a hypersaline and more distal lake environments mainly under oxic conditions. OM accumulation in both organic facies was primarily controlled by the paleo-redox conditions rather than paleo-productivity. By contrast, there is no significant difference between organic facies A and B samples with respect to the paleoclimate proxies. Generally, the sediments were deposited under arid/cold conditions with weak chemical weathering during the Pleistocene. The soils on the Tibetan Plateau tended to be alkaline at this time. Combined with the published data, the Pleistocene indices based on GDGT biomarkers indicate a rather continuous cooling and aridification process from Miocene to present. The Pleistocene Mean Annual Air Temperature based on *b*GDGTs (0.54-4.91 °C, 2.23 °C on average) was slightly higher than the present temperature, and the reconstructed lake surface temperature ranges from 5.7 to 19.6 °C (in winter 2.4-13.7 °C).

### **5.2 Introduction**

Climate change in Asia was affected significantly by altitude changes of the Tibetan Plateau (TP) (Raymo and Ruddiman, 1992; Kutzbach et al., 1993). The TP is not only a controlling factor of the Asian winter and summer monsoons, but also blocks the northward flow of the warm and wet air coming from the Indian Ocean, therefore strongly influencing the climate of continental Asia. Quantitative reconstruction of the paleo-elevation of the TP is of great significance in the study of the process of mountain uplift and in turn its influence on climate and environment (Garzzone et al., 2000a, b). For example, strontium isotopes of samples from the Indian Ocean and the Himalayan foreland have been

employed as indicators that suggest links between climate change and topography of the TP (e.g., Edmond, 1992; Derry and France-Lanord, 1996). Further, the evolution of climate and changes in intensity of monsoons is related to the glaciation in the Northern Hemisphere (An et al., 2001). A significant increase in altitude of the TP is thought to have occurred around 11-8 Ma (Harrison et al., 1992; Molnar et al., 1993; Garzione et al., 2000a, b; An et al., 2001; Dettman et al., 2003). The evolution of Asian climate from the Middle Miocene onwards can roughly be divided into three phases and has been reconstructed based on evidence from sediments from continental China and the Indian and North Pacific oceans (Sun et al., 1997, 1998; Rea et al., 1998; An et al., 2001). About 9-8 Ma ago, the Asian interior drought intensified, and the Indian and East Asian monsoons developed. Then, about 3.6-2.6 Ma ago, the East Asian summer and winter monsoons continued to get more intense, and dust transport from direction of the North Pacific increased. Starting with the onset of Pleistocene (2.6 Ma), the variability of the Indian and East Asian summer monsoon increased and its intensity attenuated, while the East Asian winter monsoon got more intense (Sun et al., 1997, 1998; Rea et al., 1998; An et al., 2001).

Sediments, as the products of weathering and sedimentation, hold records of paleo-climatic conditions. With respect to understanding these conditions during the deposition of organic matter (OM)-rich rocks, both inorganic and organic geochemical characteristics can be used. In lacustrine and continent-near marine settings, inorganic geochemical characteristics are largely determined by the composition of source material, weathering, transport distance and -processes as well as by redox conditions and salinity of the bottom water during deposition (Nesbitt, 1979). As a result, some salinity- and redox-sensitive metals can be used as proxies for the evolution of paleo-depositional conditions (Algeo and Maynard, 2004; Abanda and Hannigan, 2006), while other proxies can be used to evaluate weathering intensity and to reconstruct paleo-climatic conditions (Nesbitt et al., 1980; Nesbitt and Young, 1982). For example, biotic processes have an influence on the elemental composition of sedimentary rocks (Algeo and Maynard, 2004; Tribouvillard et al., 2006). However, major element data should be used with caution in provenance analysis and the reconstruction of climate due to the mobility of diverse elements during diagenesis (Nesbitt and Young, 1989); the concentration of each element depends on several factors rather than on a single one. Therefore, it is necessary to use multiple proxies to obtain conclusive reconstructions of past environments.

Glycerol dialkyl glycerol tetraether (GDGT) lipids are important components of microbial membrane lipids (Schouten et al., 2013), that are able to record paleo-climatic conditions (Weijers et al., 2007a,b). GDGTs are widely distributed in soils (Weijers et al., 2006a; Liu et al., 2013), peats (Weijers et al., 2006b; Stock et al., 2016), lake sediments (Loomis et al., 2011; Wang et al., 2015; Raberg et al., 2021), and ocean sediments (Schouten et al., 2002, 2003; Liu et al., 2009). The most common GDGT parameters used for reconstruction of paleo-temperatures and redox conditions include isoprenoid GDGTs and branched GDGTs, which are derived from Archaea and Bacteria, respectively (Weijers et al., 2006a). Isoprenoid GDGTs (*i*GDGTs) contain cyclopentane structures, their number

being controlled by the temperature prevailing during archaea growth (Schouten et al., 2002). Branched GDGTs (*b*GDGTs) generally contain two to six methyl branched chain structures and one to two cyclopentane structures. The degree of methylation and cyclisation of the branched tetraethers is related to Mean Annual Air Temperature (MAAT) and pH of soils. The cyclization ratio (CBT) of branched tetraethers is established to indicate paleo-soil pH, while the methylation index (MBT) of branched tetraethers indicates both MAAT and pH; the MBT/CBT is commonly used as a paleo-temperature index (Weijers et al., 2007b). However, there may be a large deviation between the reconstructed regional temperature and the actual temperature in different areas. Thus, it is necessary to establish a regional conversion equation (Yang et al., 2015a). A further application of the MBT/CBT proxy is in paleo-altimetry reconstruction, on the two prerequisites that i) MBT has a good correlation with MAAT and ii) MAAT has a stable temperature lapse rate along a given altitudinal transect (Sinninghe Damsté et al., 2008; Peterse et al., 2009; Anderson et al., 2014; Yang et al., 2015b). At present, only few studies on the relationship between GDGT indices and altitude are available and are regionally concentrated on the Xiangpi Mount region, located southeast of the Qaidam Basin (Liu et al., 2013) and the region north of the Himalayas (Deng et al., 2016).

Climate change can trigger changes in lake levels and plant growth rates in adjacent catchment areas, which causes variation of paleo-salinity and OM composition. During arid periods, terrestrial input tends to be decreased, and water salinity increased with the possible development of stratified water columns. On the contrary, higher precipitation increases the input of terrigenous detrital mineral matter and OM as well as nutrients to the lake (Qiao et al., 2021a, b).  $\delta^{13}\text{C}_{\text{org}}$  values can be used as a criterion for differentiating the origin of OM (Meyers, 1997; Lamb et al., 2006). Furthermore, the TOC/TN ratio can be used to differentiate between terrestrial and aquatic OM input into a lake system (Meyers, 1997). Therefore, combining TOC/TN ratio with  $\delta^{13}\text{C}_{\text{org}}$  values has been used to assess the sources of OM (Lamb et al., 2006).

The Qaidam Basin, located on the north-eastern TP (Fig. 5.1), is a natural experimental field for the study of GDGTs due to its special arid environment. The distributions and the environmental responses of GDGTs in soils and recent lake sediments in the north-eastern TP have been studied thoroughly (Wang et al., 2012, 2013a, b; Liu et al., 2013; Dang et al., 2016; Ding et al., 2016; Li et al., 2016; Sun et al., 2016). However, for older geological periods, it is still necessary to evaluate whether GDGTs can be effectively used as records of paleo-environments. At present, there are only few reports on GDGTs of older strata on the Tibetan Plateau. For example, Xie et al. (2012) studied the tectonic uplifting of the Tibetan Plateau during the Late Miocene by using drought signals recorded by an aridity proxy ( $R_{\text{i/b}}$ ;  $\Sigma\text{iGDGTs}/\Sigma\text{bGDGTs}$ ) in the Zhada Basin. In recent years, new structures (6 methyl isomers, etc.) and new indices of GDGTs have been detected and developed, and a lot of refining has been done on the existing indices (De Jonge et al., 2014; Ding et al., 2016).

Fig. 5.1. (a) Schematic map showing the location of the Qaidam Basin in China, (b) its geological setting and sample well locations, and (c) cross sections in SE-NE and NW-SE directions (see b for position on the map). The dashed line with an arrow illustrates the depocenter shift during the depositional history of the basin (Qiu et al., 2013).

Note: the different well symbols correspond to the different locations.

This study focuses on the distribution of GDGTs, stable isotopes and major and trace elements of Pleistocene mudstones from the Central Qaidam Basin in the northeast of the Tibetan Plateau, aiming to reconstruct paleo climatic and redox conditions during this episode.

### 5.3 Geological setting

The Qaidam Basin is located at the northern edge of the Tibetan Plateau covering an area of about 120,000 km<sup>2</sup> at an elevation of 2.7 to 3.5 km. The rhomb-shaped intermontane basin is surrounded by large-scale faults creating a high relief towards three mountain ranges: the Eastern Kunlun Mountain in the south, the Altyn Tagh Range in the northwest, and the Qilian Mountains in the east (Tapponnier et al., 2001; Fang et al., 2007; Fig. 5.1a). During the Mesozoic and Cenozoic a 3 to 16 km thick sedimentary succession, mainly of lacustrine origin, was deposited (Pang et al., 2005; Jian et al., 2013; Qiao et al., 2021a). The Mesozoic tectonic regime was characterized by the evolution of the Tethys and Mongol–Okhotsk Oceans and by the collision of related tectonic units (Gehrels et al., 2011).

The initial formation and evolution of the basin was controlled by syn-sedimentary basement faults during the Mesozoic; each part of the basin evolved into a combined major depression during the Paleogene-Neogene. During the Quaternary, inversion and folding took place in the midwestern part of the basin and subsidence in the eastern part (Dang et al., 2008). The tectonic evolution of the Cenozoic basin is characterized by the collision of the Indian and Eurasian plates. The depocentre moved from the northern part during the Jurassic westwards during the Paleogene-Neogene, and then towards the east during the Pleistocene (Pang et al., 2005). The Qaidam Basin can be divided into four main structural units; the West and North Qaidam Uplifts and the Sanhu and Yiliping Depressions (Fig. 5.1b; Bao et al., 2017). In the Early Pleistocene, a thick succession of fluvial-deltaic sediments was deposited. During the Middle Pleistocene, the paleo-lake reached its maximum depth, leading to deposition of mainly fine-grained argillaceous sediments. Then, in the Late Pleistocene, and under the influence of the recent tectonic movements, the central part of the basin was continuously uplifted (Dang et al., 2008).

The Pleistocene Qigequan Formation ( $Q_{1+2}$ ), which is the subject of this study, reaches thicknesses between 1.7 and 3.4 km, and was deposited at high sedimentation rates of around 650 to 800 m/Ma (Fig. 5.1c, d; Dang et al., 2008; Shuai et al., 2013; Zhang et al., 2013a).

Based on seismic data, the  $Q_{1+2}$  can be divided into 14 intervals ( $K_0$ - $K_{13}$ ; Fig. 5.2). The lithology of  $Q_{1+2}$  Formation is dominated by silty mudstones, mudstones, siltstones, and muddy limestones as well as some thin halite layers of up to 2.0 m thickness. Under the influence of the tectonic movements during the Late Pleistocene, about 500 m of the succession was eroded in the northernmost part of the Sanhu Slope (Fig. 5.1a, b; Zhang et al., 2013a). This study focuses on Pleistocene samples from the central part of the basin, where large gas fields developed, sourced from and trapped in near-shore, shallow, lacustrine sediments (Fig. 5.1b; Shuai et al., 2013; Zhang et al., 2013a; Wang et al., 2015).

Fig. 5.2. Generalized Pleistocene stratigraphic column for the study area (modified after Jian et al., 2013; Zhang et al., 2013a).

## 5.4 Material and methods

30 samples have been investigated on which organic geochemical and petrographic characteristics have been studied in detail previously (Fig. 5.1). Two different organic facies (A and B) are distinguished based on these characteristics, indicating completely different depositional environments (for more detailed see Qiao et al., 2021a).

### 5.4.1 Kerogen Concentration

14 samples were selected to obtain total organic matter concentrates. First, the powdered samples were treated with 32% hydrochloric acid (HCl) to remove carbonates and then were neutralized. Thereafter, concentrated hydrofluoric acid (HF) was used to remove silicates. Finally, the residues were neutralized again with water and air-dried. During the process, the materials were not exposed to oxidizing agents or high temperature.

### 5.4.2 Elemental analysis

Before the measurement of major and trace elements, fresh core samples were pulverized to a mesh size of < 200 using a tungsten carbide ball mill. Major elements were analyzed using an ARL Perform' X 4200 wavelength-dispersive X-ray fluorescence (WD-XRF) spectrometer. Loss on ignition (LOI) was achieved by heating 1 g of powder at 1100 °C for one hour. Analytical precision was better than 1%.

The relative concentration of trace elements of bulk rock samples was determined via an ELAN DRC-e inductively coupled plasma mass spectrometer (ICP-MS). Before the insertion into the ICP-MS, powders were digested with a mixed solution of HF/HNO<sub>3</sub> in high-pressure Teflon bombs, and then heated to 190 °C for 48 h. Internal and international standards (BH-VO2, AGV-2, BCR-2 and GSP-1 (USGS)) were used for calibration and three duplicates were analyzed to invest the accuracy of the measurements. Analytical accuracy and precision are 10% and 5%, respectively.

The measurement of total organic (TOC) and inorganic (TIC) carbon contents of the kerogen concentrates were performed using a Liqui TOC II analyzer (Elementar). In addition, total sulfur (TS) content was analyzed using a Leco S 200 sulfur analyzer. Further information on these analyses is published in Qiao et al. (2020 and 2021b). The elemental compositions of kerogen (C, N, H) were analyzed by using a LECO-CHN-628 based on DIN 51732.

#### 5.4.3 Rock-Eval pyrolysis

Rock-Eval pyrolysis was performed on the kerogen concentrates using a Rock-Eval VI instrument (Vinci Technologies) following the procedure describe in detail in Behar et al. (2001). The measured parameters include S<sub>1</sub> (volatile/sorbed hydrocarbon content, mg HC/g rock), S<sub>2</sub> (remaining hydrocarbon generative potential, mg HC/g rock), and T<sub>max</sub> (temperature of maximum pyrolysis yield, °C). Hydrogen index (HI = S<sub>2</sub>/TOC, mg HC/g TOC) was calculated.

#### 5.4.4 Organic geochemical analyses

##### 5.4.4.1 Experimental Methods

Aliquots of 10-15 g of pulverized sample were extracted by ultra-sonication for 15 min and subsequent stirring for 15 min at room temperature. The extraction was performed sequentially using methanol (50 mL), a mixture of methanol and dichloromethane (1:1, vv; 50 mL), and dichloromethane (50 mL), respectively. The combined raw extracts were concentrated using rotary evaporation to a volume of 1 mL, dried by addition of ca. 2 mg of sodium sulfate and evaporated to dryness under a gentle stream of nitrogen at room temperature. Prior to fractionation, the extracts were re-dissolved in a mixture of 0.5 mL of *n*-pentane and 300 µL of DCM. Fractionation was performed by column chromatography using microcolumns with activated silica gel (2 g) and eluents of increasing polarity resulting in three fractions: 5 mL of *n*-pentane/DCM (40:60, v:v); 5 mL of DCM; and 5 mL of methanol/DCM (1:1, v:v). The third fraction, containing the GDGTs, was evaporated to dryness under a gentle stream of nitrogen, re-dissolved in 400 µL of a mixture of *iso*-propanol/*n*-hexane (1:99, v:v), and finally filtered over a 0.4 µm polytetrafluoroethylene (PTFE) filter. Liquid chromatography-mass spectroscopy was conducted with a Thermo Finnigan MAT LCQ-MS equipped with an APCI ion source and a cyanid-column (3µm, 150×3 mm) with a scanning range of 950 to 1450 *m/z*. Nitrogen was used as carrier gas.

##### 5.4.4.2 Calculation of GDGTs proxies

Different indices including the branched isoprenoid tetraether (BIT; Hopmans et al., 2004), the methylation of branched tetraether MBT<sup>(i)</sup> (after Weijers et al., 2007b; Peterse et al., 2012), CBT

(cyclisation of branched tetraether after Weijers et al., 2007b), and the TetraEther index of tetraethers consisting of 86 carbon atoms (TEX<sub>86</sub>; Schouten et al., 2002) were calculated following the equations (5.1)-(5.5).

$$\text{BIT} = \frac{b\text{GDGT III} + b\text{GDGT II} + b\text{GDGT I}}{b\text{GDGT III} + b\text{GDGT II} + b\text{GDGT I} + \text{crenarchaeol}} \quad (5.1)$$

$$\text{MBT} = \frac{b\text{GDGT I} + b\text{GDGT Ia} + b\text{GDGT Ib}}{b\text{GDGT I} + b\text{GDGT Ia} + b\text{GDGT Ib} + b\text{GDGT II} + b\text{GDGT IIa} + b\text{GDGT IIb} + b\text{GDGT III} + b\text{GDGT IIIa} + b\text{GDGT IIIb}} \quad (5.2)$$

$$\text{MBT}' = \frac{b\text{GDGT I} + b\text{GDGT Ia} + b\text{GDGT Ib}}{b\text{GDGT I} + b\text{GDGT Ia} + b\text{GDGT Ib} + b\text{GDGT II} + b\text{GDGT IIa} + b\text{GDGT IIb} + b\text{GDGT III}} \quad (5.3)$$

$$\text{CBT} = -\log \left( \frac{b\text{GDGT Ia} + b\text{GDGT IIa}}{b\text{GDGT I} + b\text{GDGT II}} \right) \quad (5.4)$$

$$\text{TEX}_{86} = \frac{i\text{GDGT}-2 + i\text{GDGT}-3 + \text{Cren}'}{i\text{GDGT}-1 + i\text{GDGT}-2 + i\text{GDGT}-3 + \text{Cren}'} \quad (5.5)$$

Several calibrations for lake surface temperature (LST) and specific calibrations for summer (SLST) and winter lake surface temperature (WLST) from global and regional studies have been proposed, i.e. the equation (5.6)-(5.11) (Powers et al., 2010; Tierney et al., 2010a; Castañeda and Schouten, 2011; Pearson et al., 2011; Sun et al., 2011).

$$\text{LST}_{\text{Powers2010}} = 50.8 \times \text{TEX}_{86} - 10.4 \quad (5.6)$$

$$\text{SLST}_{\text{Powers2010}} = 46.6 \times \text{TEX}_{86} - 5.6 \quad (5.7)$$

$$\text{WLST}_{\text{Powers2010}} = 57.3 \times \text{TEX}_{86} - 17.5 \quad (5.8)$$

$$\text{LST}_{\text{Tierney2010}} = 38.87 \times \text{TEX}_{86} - 3.50 \quad (5.9)$$

$$\text{LST}_{\text{Castañeda2011}} = 54.89 \times \text{TEX}_{86} - 13.36 \quad (5.10)$$

$$\text{LST}_{\text{Kim2008}} = 56.2 \times \text{TEX}_{86} - 10.78 \quad (5.11)$$

MAAT (mean annual air temperature) was calculated based on assumptions and calibrations for both soils and lake sediments. Based on a globally distributed soil calibration (Weijers et al., 2007b), MAAT can be obtained using Eq. 5.12. This calibration was extended and revised with the transfer function (Eq. 5.13) proposed by Peterse et al. (2012). The MAAT proxy based on the distribution of *b*GDGTs in global soils was calculated following the equation of De Jonge et al. (2014) (5.14 and 5.15). In addition, a calibration for soil-derived GDGTs on the Tibetan Plateau (Günther et al., 2014) was applied (5.16).

$$\text{MAAT}_{\text{Weijers2007 (G)}} = \frac{\text{MBT} - 0.12 - 0.19 \times \text{CBT}}{0.02} \quad (5.12)$$

$$\text{MAAT}_{\text{Peterse2012}} = 0.81 - 5.67 \times \text{CBT} + 31.0 \times \text{MBT}' \quad (5.13)$$

$$\text{MAAT}_{\text{De Jonge 2014}} = 7.17 + 17.1 \times [\text{I}] + 25.9 \times [\text{Ib}] + 34.4 \times [\text{Ic}] - 28.6 \times [\text{II}] \quad (5.14)$$

$$\text{MAAT}_{\text{De Jonge 2014}'} = -8.15 + 31.45 \times \text{MBT}' \quad (5.15)$$

$$\text{MAAT}_{\text{Günther 2014}} = -3.84 + 9.84 \times \text{CBT} + 5.92 \times \text{MBT}' \quad (5.16)$$

Several global and regional lake temperature calibration studies have been proposed for African (Tierney et al., 2010a; Loomis et al., 2012), Chinese and Nepalese lakes (Sun et al., 2011) and lakes along a transect from the Scandinavian Arctic to Antarctica (Pearson et al., 2011):

$$\text{MAAT}_{\text{Tierney2010}} = 11.84 + 32.54 \times \text{MBT} - 9.32 \times \text{CBT} \quad (5.17)$$

$$MAAT_{Tierney2010} = 50.57 - 74.28 \times [III] - 31.60 \times [II] - 34.79 \times [I] \quad (5.18)$$

$$MAAT_{Sun2011} = 4.0 + 38.2 \times MBT - 5.6 \times CBT \quad (5.19)$$

$$MAAT_{Pearson2011} = 20.9 + 98.1 \times [Ib] - 12.0 \times [II] - 20.5 \times [III] \quad (5.20)$$

$$MAAT_{Loomis2012} = 22.77 - 33.58 \times [III] - 12.88 \times [II] - 418.53 \times [IIc] + 86.43 \times [Ib] \quad (5.21)$$

Moreover, the following equations were applied to calculate soil-pH based on *i*GDGTs from global and regional studies (Tierney et al., 2010a; Sun et al., 2011; De Jonge et al., 2014), including calibrations for the Tibetan Plateau (Günther et al., 2014).

$$pH_{Günther2014} = 7.97 + 2.78 \times CBT \quad (5.22)$$

$$pH_{DeJonge2014} = 7.9 - 1.97 \times CBT \quad (5.23)$$

$$pH_{Weijers2007} = (3.33 - CBT)/0.38 \quad (5.24)$$

$$pH_{Tierney2010} = 10.32 - 3.03 \times CBT \quad (5.25)$$

$$pH_{Sun2011} = 8.98 - 1.72 \times CBT \quad (5.26)$$

The following equations were used to evaluate aridity conditions:

$$\text{Aridity proxy } R_{i/b} \text{ (Xie et al., 2012)} = \Sigma iDGETs / \Sigma bDGETs \quad (5.27)$$

$$\#rings_{tetra} \text{ (Sinninghe Damsté, 2016)} = ([Ib] + 2 \times [Ic]) / ([Ia] + [Ib] + [Ic]) \quad (5.28)$$

#### 5.4.5 Carbon and nitrogen isotopes

Carbon and nitrogen isotope measurements were carried out on kerogen concentrates. Around 0.05-0.1 mg isolated kerogen was weighed into tin capsules. The measurements were performed on a Delta V Advantage isotope ratio mass spectrometer linked to a Flash EA IsoLink™ combustion elemental analyzer. The  $\delta^{13}C$  and  $\delta^{15}N$  values are given relative to the international VPDB (Vienna Pee Dee Belemnite) and AIR standards. International reference materials USGS 24 and USGS 40 ( $\delta^{13}C$ ), IAEA N1 and IAEA N2 ( $\delta^{15}N$ ) were used to monitor analytical performance.

## 5.5 Results

### 5.5.1 Elemental composition

The major and trace elemental concentrations of the bulk samples are shown in Table 5.1. Ratios of  $SiO_2/Al_2O_3$  (2.67-4.58) and  $Fe_2O_3/K_2O$  (1.27-3.13) (Table 5.2) are in accordance with the typical ratios observed in shales (Herron, 1988). Their compositions normalized to Post-Archean Australian Shale (PAAS) (Taylor and McLennan, 1985) are shown in Fig. 5.3. Compared to the PAAS, the Pleistocene source rocks are depleted in  $SiO_2$ ,  $TiO_2$ ,  $Al_2O_3$ ,  $Fe_2O_3$ ,  $K_2O$ , and enriched in  $Na_2O$ . The relative concentrations of  $CaO$  and  $P_2O_5$  vary around the PAAS value in two organic facies samples (Fig. 5.3). Relative to the PAAS, Rb, Th, Mn and Ga are depleted only in organic facies A. Sr is enriched in organic facies B and U and Mo in organic facies A. Ba shows a larger variation in organic facies B compared to that in organic facies A (Fig. 5.3). Enrichment factors (EF) for trace elements (X) were calculated as:

$$X_{EF} = (X/Al)_{sample} / (X/Al)_{PAAS} \quad (5.29)$$

Fig. 5.3. Major and trace elements normalized to Post-Archean Australian Shale (PAAS; Taylor and McLennan, 1985) for the Pleistocene source rocks.

The TOC, TIC, and TS data of the whole rock samples can be found in a previously published study (Qiao et al., 2021a). The elemental composition of the concentrated kerogen are shown in Table 5.3. The TOC and TIC contents of the isolated kerogen for the organic facies A samples are 22.44-48.16 wt.% TOC with an average value of 33.79 % and 0.02-0.07 wt.% TIC with an average of 0.04 wt.%, respectively (Table 5.3). TIC values close to zero are expected after HCl treatment. The TS values for organic facies A are 2.17-9.80 wt.% with an avg. of 5.44 wt.%.

Kerogen from organic facies A samples has both high C/N atomic ratios of 25.18-33.76 and C/S atomic ratios of 7.40–40.15 (Table 5.3). H/C atomic ratios of organic facies A are 1.30–1.61 (1.44 on average) and thus in a typical range for kerogen (Table 5.3). TOC, TIC, TS and elemental composition in terms of hydrogen, and nitrogen contents for the organic facies B samples could not be measured accurately due to the poor kerogen concentrations and are thus not reported here.

Table 5.1. Major and trace elements concentrations of the Pleistocene lacustrine mudstone.

Well	Interval	Sample ID	Depth (m)	Organic facies	TOC (%)	Major elements (%)								Trace elements (ppm)							
						SiO <sub>2</sub>	TiO <sub>2</sub>	Al <sub>2</sub> O <sub>3</sub>	Fe <sub>2</sub> O <sub>3</sub>	CaO	Na <sub>2</sub> O	K <sub>2</sub> O	P <sub>2</sub> O <sub>5</sub>	Ga	Mn	Rb	Sr	Mo	Ba	Th	U

In this study,  $CIA_{corrected} = [Al_2O_3 / (Al_2O_3 + CaO^* + Na_2O) \times (100 - 8.5)]$  for the Cenozoic mudstones, where  $Na_2O$ ,  $Al_2O_3$ , and  $CaO^*$  are molar concentrations, and 8.5 represents the molecular percent of  $K_2O$  of the unweathered Cenozoic source rocks in the Qaidam Basin (Jian et al., 2013). If the  $CaO^* \leq Na_2O$ ,  $CaO^*$  is considered as the  $CaO$  of silicate fraction; while if the  $CaO^*$  greater than  $Na_2O$ , the proportion of  $Na_2O$  is considered as the proportion of  $CaO$  of silicate fraction (Nesbitt and Young 1982; McLennan 1993). Authigenic U = total U- Th/3 (Jones and Manning, 1994).

Table 5.3. Isotopic, elemental\* and Rock-Eval data of the kerogen from Pleistocene biogenic gas source rocks in the central Qaidam Basin, China.

\*For facies B, only data which were not affected by precipitation of fluorinated compounds during HF treatment are presented.

### 5.5.2 Rock-Eval pyrolysis

The Rock-Eval results of the kerogen concentrates are listed in Table 5.3 for organic facies A only. For organic facies B, only the TOC normalized HI values as well as  $T_{\max}$  values are listed due to problems with kerogen concentration (precipitation of fluorinated compounds). HI and  $T_{\max}$ , however, are not affected. For organic facies A,  $S_1$  and  $S_2$  values range from 1.71 to 9.69 (mean value = 4.95) and from 52.47 to 116.07 (mean value = 91.53 mg HC/g rock), respectively. Average  $T_{\max}$  values are 412 and 375 °C for facies A and B indicating immature organic matter, while average HI values are at 268 and 106 mg/g TOC, respectively, indicating the presence of type III kerogen.

### 5.5.3 Distribution pattern of GDGTs

Fig. 5.4. structures and molecular ion  $m/z$  values for glycerol dialkyl glycerol tetraethers (GDGTs) (taken from Li et al., 2016).

GDGTs have been detected in nine out of fourteen samples. Among them, three samples came from the organic facies A group and six samples from the organic facies B group. Unlike other parameters, the distribution patterns of GDGTs are very similar in both organic facies groups. GDGT numbers refer to structures shown in Li et al. (2016) (Fig. 5.4). In this study, both *b*GDGTs and *i*GDGTs can be recognized, and the concentrations of *b*GDGTs are higher than those of *i*GDGTs in most samples with  $R_{i/b}$  index values of 0.77-3.35 (Table 5.4). The proportions of each *i/b*GDGT to all *i/b*GDGTs are listed in Table 5.4 ( $R_{i/b}$ ).

Fig. 5.5. The ternary diagram of the *bGDGTs* type I, II, III (data from De Jonge et al., 2014; Sinninghe Damst  et al., 2016; Crampton-Flood et al., 2021).

*bGDGTs* are mainly show as *GDGT* II followed by *GDGT* I and III (Fig. 5.5 and Fig. 5.6; Table 5.4). In addition, *bGDGTs* without cyclopentane moieties (*bGDGT*I, -II, and -III) were generally more abundant than cyclopentane ring-containing *bGDGTs* (Fig. 5.6). MBT indices are 0.17-0.34, and MBT' values are almost identical to MBT because of the low concentration of *GDGT*IIIb and -IIIc for all samples (Table 5.5). CBT and BIT values are 0.31-0.76 and 0.72-1.00, respectively (Table 5.5).

Five *iGDGTs* were detected. *GDGT*-0 is the most abundant *iGDGT* (56.82–85.22 % of *iGDGTs*) (Table 5.4). The concentrations of *iGDGTs* with cyclopentane(s) moieties (*iGDGT* 1–3) decrease from *iGDGT* 1 to *iGDGT* 3 with overall low concentrations (Fig. 5.6). The relative abundance of crenarchaeol shows a complex pattern (Table 5.4). *iGDGTs* 1–3 is generally more abundant than crenarchaeol, but the proportion of *iGDGT*-1 is lower than that of crenarchaeol in samples 18-872, 18-879 and 18-880 (Table 5.4). Furthermore, crenarchaeol concentrations are lower than *iGDGTs* 0–3 in samples 18-853, 18-867, 18-878 and 18-897 (Table 5.4). The related proxy of  $\text{TEX}_{86}$  ranging from 0.35 to 0.54 (avg. 0.47) shows little variations (Table 5.5).

Fig. 5.6. Fractional abundance of *GDGT* I–III *GDGT* 0–3, crenarchaeol, crenarchaeol', as fractions of the sum of all pictured *GDGTs* (*bGDGTs* as well as *iGDGTs*).

#### 5.5.4 Carbon and nitrogen isotope

Carbon isotope data in the kerogen concentrates clearly differ in the samples of the two organic facies.  $\delta^{13}\text{C}$  values vary from  $-27.16$  to  $-28.49$  ‰ VPDB (avg.  $-27.79$  ‰ VPDB) and  $\delta^{15}\text{N}$  values from  $2.23$  to  $4.38$  ‰ air (avg.  $3.40$  ‰ air) in organic facies A samples. For organic facies B samples,  $\delta^{13}\text{C}$  values vary from  $-22.50$  to  $-24.65$  ‰ VPDB (avg.  $-23.63$  ‰ VPDB) while  $\delta^{15}\text{N}$  values could not be measured accurately due to the low N concentrations and are thus not reported here (Table 5.3).

### 5.6 Discussion

#### 5.6.1 Origin of organic matter

Fig. 5.7. Typical  $\delta^{13}\text{C}$  and C/N ranges for organic inputs (after Lamb et al., 2006). Note: sample symbols represent sample locations (Fig. 5.1b).

$\delta^{13}\text{C}_{\text{org}}$  can be used to distinguish continental and marine plant sources of OM and even to identify types of land plants as well (Meyers, 1997). Lamb et al. (2006) proposed that  $\delta^{13}\text{C}$  and C/N ratios in organic material are useful indicators to deduce depositional environments and OM origin. Fig. 5.7 indicates that the OM of organic facies A is mainly derived from a mixture of  $\text{C}_3$  higher plants and freshwater dissolved organic carbon (DOC) which indicates a mixture of higher plants and phytoplankton in lacustrine environments (Rashid, 1985; Lamb et al., 2006). In addition, the  $\delta^{15}\text{N}_{\text{org}}$  value is an indicator distinguishing land-plant and algal sources of OM, because  $\delta^{15}\text{N}_{\text{org}}$  values of plankton ( $\delta^{15}\text{N}_{\text{org}}$  of  $+8.6$ ‰) are higher than those of  $\text{C}_3$  plants ( $\delta^{15}\text{N}_{\text{org}}$  of  $+0.4$ ‰) (Peterson and Howarth,

1987).  $\delta^{15}\text{N}$  values between 2 and 4‰ in organic facies A samples thus also indicate a mixture of  $\text{C}_3$  plants and phytoplankton. These findings are basically in agreement with petrographic and biomarker data as well as Rock-Eval data (Qiao et al., 2021a), indicating the OM in organic facies A samples mainly derives from macrophytes growing at the lake margin, such as submerged angiosperms, freshwater mosses, non-marine algae, and lichens. This conclusion is also consistent with the  $\text{C}_3$  plant distribution during the late Pliocene and the current dominance of  $\text{C}_3$  vegetation in the TP (Wang et al., 2008). It should be noticed that the OM is in reality derived from multiple sources; thus the average  $\delta^{13}\text{C}_{\text{org}}$  value of each sample indicates the major origin of OM and cannot exclude other minor sources, such as bacteria.

### 5.6.2 Depositional conditions within the water column

Fig. 5.8. (a) Sr/Ba and (b) Sr vs. CaO indicating paleo-salinity of the Pleistocene source rocks from the Qaidam Basin, China. Note: sample symbols represent sample locations (Fig. 5.1b).

Salinity plays an important role in aquatic organism community composition in lake systems (Romero-Viana et al., 2012). Organic facies A was deposited in a shallow freshwater environment, probably without stratification, which is supported by the moderate H/C ratios in combination with high C/S ratios for organic facies A kerogen (Table 5.3) and the relatively low  $\delta^{13}\text{C}$  values (Lamb et al., 2006). By contrast, organic facies B developed in a hypersaline depositional environment; a first indicator are the rather high  $\delta^{13}\text{C}$  values (Lamb et al., 2006). Moreover, different paleo-salinities during deposition of the two organic facies are also indicated by Sr/Ba ratios. Wei and Algeo (2020) considered that it is necessary to exclude carbonate-hosted Sr when using Sr/Ba ratios as a paleo-salinity proxy. In this study, around 140 ppm are bound to silicates rather than carbonate based on the y-intercept in Fig. 5.8b. For organic facies A samples this finding indicates freshwater conditions (silicate-bound Sr/Ba ratios are 0.11-0.24) (Fig. 5.8a; Wei and Algeo, 2020). However, almost all Sr is carbonate-hosted in organic facies B samples (Fig. 5.8b), and thus cannot be used as an indicator of paleo-salinity. The above conclusion supports the results based on the TOC/TS ratios and biomarker characters in a previous study (Qiao et al., 2021a).

Fig. 5.9. (a) U/Th ratio vs. authigenic U to interpret paleo-redox conditions. (b)  $U_{EF}$  vs.  $Mo_{EF}$  (General patterns of  $U_{EF}$  vs.  $Mo_{EF}$  covariation is modified after Tribovillard et al. (2012)). (c) Comparison of TOC–Mo relationship between results of this study, Barnett Formation in the Fort Worth Basin and those of modern anoxic silled-basin environments (The TOC–Mo regression line slopes and previous studies data are given in Rowe et al. (2008). Note: the TOC contents used in Rowe et al. (2008) are original TOC<sub>0</sub> (TOC<sub>0</sub> = TOC<sub>meas</sub>/(1–0.363), so the slope for the Fort Worth Basin should be a little bit steeper). (d) Estimation of deep-water renewal time (years) during Pleistocene source rocks deposition using estimates from modern anoxic silled basins and the Barnett Formation in the Fort Worth Basin. Note: sample symbols represent sample locations (Fig. 5.1b). (e) TS/Fe vs.  $Al_2O_3/TOC$  and (f) TS/Mn vs.  $TiO_2/TOC$  to interpret paleo-redox conditions (modified after Cichon-Pupienis, et al., 2020). Note: sample symbols represent sample locations (Fig. 5.1b).

Besides paleo-salinity, paleo-redox conditions can also affect productivity and preservation of OM. The plot of U/Th ratios vs. authigenic U values (authigenic U = total U–Th/3; Jones and Manning, 1994; Fig. 5.9a) indicates dysoxic to slightly anoxic bottom water conditions for organic facies A samples and oxic conditions for organic facies B samples (Fig. 5.9a), i.e. there is a major difference between organic facies A and B, separating them clearly. The same results are inferred from  $Mo_{EF}$  vs.  $U_{EF}$  co-variation (Fig. 5.9b; see results for calculation of enrichment factors). Both U and Mo are enriched under oxygen-

depleted and even more under anoxic conditions. However, enrichment of Mo relative to U is enhanced under sulfidic conditions, i.e. when bottom water contains hydrogen sulfide (Algeo and Tribovillard, 2009; Tribovillard et al., 2012). The grey zone (Fig. 5.9b) indicates the “unrestricted marine” (UM) trend where the  $Mo_{EF}$  vs.  $U_{EF}$  co-variation is controlled by redox conditions at the sediment/water interface. Facies B samples plot clearly in the oxic zone, where little or no enrichment of Mo and U takes place, while facies A samples follow the trend of suboxic to anoxic conditions showing modest enrichment factors for both elements (Fig. 5.9b). It is interesting to note that the principles developed for marine settings can also be applied for the lacustrine setting of the Pleistocene in the Qaidam Basin. Differences, however, exist as well, e.g. Mo/TOC and U/TOC ratios are much lower in the Qaidam Basin sediments, which is certainly related to lake water chemistry (lower U and Mo concentrations compared to sea water) and high bioproductivity.

Anoxic environments are also indicated by the clear positive relationship between Mo and TOC contents in most organic facies A samples (Fig. 5.9c), because the presence of  $H_2S$  can prompt Mo to be easily sorbed by OM (Helz et al., 1996; Zheng et al., 2000; Tribovillard et al., 2012). It should be noted that the Mo/TOC ratios in both organic facies A and B samples are even lower than those in recent Black Sea sediments (Fig. 5.9c and d) indicating strongly restriction conditions. However, this conclusion is not necessarily valid here due to the different Mo concentrations in the non-marine setting and also by the high sedimentation rate in the basin (0.65 to 0.8 km/Ma on average; Dang et al., 2008; Shuai et al., 2013; Zhang et al., 2013a). Low Mo/TOC ratios giving misleading information related to basinal restriction are also reported for Telychian sediments recently (Cichon-Pupienis et al., 2021). This anomaly may be due to three reasons. First, the high sedimentation rate may lead to faster removal of sediments from the contact of the overlying water column (Liu and Algeo, 2020) during periodic/occasional fresh-water influxes carrying large amounts of terrigenous debris, i.e., relatively well ventilated bottom waters was not favorable for trace metal uptake in sediments. Second, terrestrial debris supply was limited during periods of high water evaporation, thus limiting the amount of e.g. Mo and U that was transported towards the sediment/water interface, therefore, leading to a relative depletion of such elements per unit volume of OM. Third, the study area did not develop a persistent and extensive  $H_2S$  rich bottom water. Conversely, the positive relationship between Mo and TOC contents is not observed in organic facies B (Fig. 5.9c), indicating an oxic depositional environment. Ghassal et al. (2018) proposed using the TS/Fe vs.  $Al_2O_3$ /TOC ratios and TS/Mn vs.  $TiO_2$ /TOC ratios as proxies to indicate terrigenous input and redox conditions. Later, Cichon-Pupienis et al. (2020) used these proxies to interpret redox conditions at the sediment-sea water interface. For our Pleistocene samples, the TS/Fe vs.  $Al_2O_3$ /TOC (Fig. 5.9e) and TS/Mn vs.  $TiO_2$ /TOC (Fig. 5.9f) diagrams indicate oxygen-depleted conditions for organic facies A samples and oxygen-rich bottom water conditions for organic facies B samples (i.e., higher  $Al_2O_3$ /TOC and  $TiO_2$ /TOC ratios), which is in accordance with the other parameters discussed above. Moreover, a reducing sediment/water interface is also indicated for organic facies A by high  $C_{org}/P$  ratios (108.11-1375.11) and an oxidizing environment for organic

facies B by low  $C_{org}/P$  ratios (31.53-82.95) (Table 5.2), respectively (Algeo and Ingall, 2007; Algeo and Li, 2020). The above results are consistent with the relative concentrations of TOC, TS and iron (Qiao et al., 2021a).

### 5.6.3 Factors controlling OM preservation and accumulation

Paleo-redox conditions and paleo-productivity are the most important factors controlling OM preservation in source rocks (Pedersen and Calvert, 1990). In addition, lateral variability in thickness and facies of source rocks depend on interacting complex physical and chemical processes not only related to OM quantity and quality. The very high sediment accumulation rates characterizing the Pleistocene section in the Qaidam Basin have been discussed in Qiao (2021a). Here we report additional evidence based on calculated source potential index. The hydrocarbon generation potential of a given formation is determined by the thickness of the source rock and its kerogen maturity, quantity as well as quality. Based on Demaison and Huizinga (1991) a source potential index (SPI; t HC/m<sup>2</sup>) can be calculated as

$$SPI = \frac{h \times (\overline{S_1 + S_2}) \times \rho}{1000} \quad (5.30)$$

In which  $h$  (m) and  $\rho$  (t/m<sup>3</sup>) are thickness and density of source rock, respectively.  $(\overline{S_1 + S_2})$  (kg HC/t rock) are average values of Rock-Eval parameters (data published in Qiao et al., 2021a).

Table 5.6 shows the calculated SPI values for the different wells under the assumption of an average density of different organic facies (the mean density is 2.10 g/cm<sup>3</sup> for organic facies A samples and 2.22 g/cm<sup>3</sup> for organic facies B samples; Qiao et al., 2021a). Except for the T2 Well which is close to Sebei 1 Gas Field (SPI value = 1.49 t HC/m<sup>2</sup>), the wells located above the gas fields show moderate to high SPI values ranging from 2.24 to 25.66 t HC/m<sup>2</sup> (Table 5.6). It should be noted that there is a rather high uncertainty with respect to the absolute values, because there the sample number is small compared to the thickness of the formation. Sampling of source rocks is often biased towards organic matter-rich layers; therefore the average  $S_1 + S_2$  value might be overestimated by more than 10 % of the value. Nevertheless, the data indicate that the studied, thick Pleistocene sequence has overall a very high source potential index. Although the periodic oxic conditions in bottom water were not in favor of OM preservation, the overall high sedimentation rates exceeding those of most marine settings by far (Qiao et al., 2021a) were the key factor for developing a very good source rock sequence (Hunt, 1996; Demaison and Moore, 1980).

The relative importance of paleo-redox conditions and paleo-productivity as control factors on OM preservation can be evaluated via the relationship between TOC content and  $\delta^{13}C_{org}$  value (Harris et al., 2004). If bioproductivity is the controlling factor,  $\delta^{13}C_{org}$  values should be positively correlated to TOC content (Hollander and McKenzie, 1991); where OM preservation is controlled by paleo-redox conditions, the relationship generally shows a negative correlation (Freeman et al., 1990, 1994; Wachniew and Róžański, 1997). Fig. 5.10 indicates that the OM preservation in both organic facies A and B was primarily controlled by the paleo-redox conditions, i.e., the dysoxic to slightly anoxic bottom

water conditions for organic facies A samples and oxic conditions for organic facies B samples might be the most important factor controlling their low and high TOC content, respectively.

Fig. 5.10. Cross plot of the carbon isotopic composition of kerogen ( $\delta^{13}C_{org}$ ) vs. total organic carbon content (TOC).  $\delta^{13}C_{org}$  shows a significant negative correlation with TOC in both facies A and B samples, indicating organic carbon deposition was controlled by redox conditions. Note: sample symbols represent sample locations (Fig. 5.1b).

Table 5.6. SPI calculated based on our studied wells.

#### 5.6.4 Paleoclimate

##### 5.6.4.1 Evidence from major and trace elements

The Asian inland began drying in the Miocene, or even late Oligocene (An et al., 2001), intensified at the early Pleistocene, which may be related to the global cooling and the TP uplift (Fang et al., 2007; Wu et al., 2011). The Chemical Index of Alteration (CIA, Nesbitt and Young, 1982) is a measure of the relative contribution of feldspars and their chemical alteration products (clay minerals) in a rock and, thus, serves as an indicator for the degree of weathering (e.g. Fedo et al., 1995; Roy and Roser, 2013). It can be applied for both, igneous as well as sedimentary rocks, whereby it rather represents the general weathering conditions of a larger provenance region for the latter ones. Fig. 5.11a shows a triangular plot of the relative composition of different oxides with  $Al_2O_3$  representing their stable parts and  $K_2O$  and  $CaO^* + Na_2O$  their labile parts.  $CaO^*$  represents only the fraction originating from silicates and not carbonates or apatite. It is calculated according to Fedo et al. (1995):

$$CaO^* = CaO - CO_2 \text{ (calcite)} - 0.5 \times CO_2 \text{ (dolomite)} - 10/3 \times P_2O_5 \text{ (apatite)} \quad (5.31)$$

Here, the ratio of dolomite/calcite is considered 0.8 (average ratio of the Qigequan Formation in the study area based on XRD data; Zhang et al., 2014) and CO<sub>2</sub> yields are obtained from TIC measurements.

Fig. 5.11. (a) A–CN–K ternary diagrams for mudstones correction for K metasomatism is made by projecting data points back onto ideal weathering pathway from K-apex (Fedo et al., 1995). (b) Discrimination diagrams of SiO<sub>2</sub> vs. (Al<sub>2</sub>O<sub>3</sub> + K<sub>2</sub>O + Na<sub>2</sub>O) after Suttner and Dutta (1986) and (c) Ga/Rb vs. K<sub>2</sub>O/Al<sub>2</sub>O<sub>3</sub> (Roy and Roser, 2013) for the Pleistocene source rocks from the Qaidam Basin. (d) The distribution of soil sample GDGTs at low altitudes (<3,400 m asl) in the central Himalayas is characterized by high MBT and low R<sub>fb</sub> values, opposite to the pattern observed for high altitudes (after Chen, et al., 2020). The characteristics of the MBT and high R<sub>fb</sub> values for the studied samples are similar to those for higher altitudes. Note: samples symbols represent sample locations (Fig. 5.1b).

The dashed line (arrow A in Fig. 5.11a) presents the regression through the studied samples, and its intersection with feldspar (Pl-Kfs) represents the unweathered rock. The solid-line (arrow B in Fig. 5.11a) represents the predicted weathering trend. CIA values are further corrected for the possible effects of diagenesis and K-metasomatism, which may cause some degree of K-enrichment in contrast to its general depletion (e.g. Nesbitt and Young, 1984; Fedo et al., 1995). This correction is performed by projecting each data point onto the Upper Archaean trend along a vector originating in the K<sub>2</sub>O corner (arrow C in Fig. 5.11a), yielding the corrected, pre-metasomatized CIA values (arrow D in Fig. 5.11a). A detailed description of the correction procedure is given by Fedo et al. (1995). The here

analyzed samples show  $CIA_{corrected}$  values of 30-65 (53 on average; Table 5.2) indicating arid/cold conditions with weak chemical weathering during the Pleistocene (Fig. 5.11a). Compared to the mean CIA values of Paleocene + Eocene (CIA 71), Oligocene (72), and Miocene (67) mudstones released by Jian et al. (2013), these new CIA values indicate a continuous cooling and aridification process.

The interpreted arid/cold conditions are further supported by Ga/Rb and  $K_2O/Al_2O_3$  ratios (Roy and Roser, 2013): Both low Ga/Rb ratio  $< 0.15$  and high  $K_2O/Al_2O_3$  ratios  $> 0.17$ -0.22 suggest abundant illite and dry/cold climatic conditions (Roy and Roser, 2013). Meanwhile, the  $K_2O/Al_2O_3$  ratios in this study are higher than 0.17; we thus propose that values higher than 0.15 to 0.17 mark arid/cold conditions, rather than 0.2 defined for the Khalaspir Gondwana Group mudstones by Roy and Roser (2013) (Fig. 5.11b). The same result is affirmed by the binary diagram between  $SiO_2$  and  $Al_2O_3 + K_2O + Na_2O$  (Fig. 5.11c). Interestingly, there is no significant difference between organic facies A and B samples with respect to these paleoclimate proxies. Our conclusions on an arid and cold climate are in line with previous publications based on evaporite minerals (Luo et al., 2018), sporopollen (Wu et al., 2011), carbonate contents and salt ion records (Zhang et al., 2013b), as well as stable hydrogen isotopic composition of leaf-wax *n*-alkanes (Zhuang et al., 2011) on rocks of the same age in the basin.

#### 5.6.4.2 Evidence from GDGTs

##### 5.6.4.2.1 GDGTs as indicator of palaeo-temperature

The current climate of the Qaidam Basin is extremely arid with the MAAT (mean annual air temperature) ranging from  $-2.5$  to  $5^\circ C$  (Herb et al., 2013; Günther et al., 2014). Considering the continuing cooling of the paleo-climate in the Qaidam Basin since the Pleistocene (Fig. 5.12; Cai et al., 2012), the Pleistocene MAAT value should be warmer than  $-2.5$ - $5^\circ C$ . Such a tendency is visible for the calculated MAATs (Fig. 5.13), but there is quite some range in the Pleistocene values, depending on the adopted equation.

Fig. 5.12. Sporopollen variations and implications for climatic conditions in the Qaidam Basin from Cai et al. (2012) with isotope data from (Lisiecki and Raymo, 2005 as shown in Cai et al., 2012). A/C: *Artemisia/Chenopodiaceae*; C+E: Xerophytic taxa (*Chenopodiaceae*+*Ephedraceae*) (%);  $\ln(NAP/AP)$ :  $\ln$  ratios of Non Arboreal Pollen (NAP) to Arboreal Pollen; Thermophilic taxa: *Betula*+*Quercus*+*Castanea*+*Juglans* (%).

Table 5.7 Related calculated results based on iGDGTs and bGDGTs.

*b*GDGTs can be produced by organisms in peats, soils, water columns and lake sediments. As a result, it is important to investigate the sources of *b*GDGTs before attempting to reconstruct the paleoclimate. Temperature reconstruction functions based on the *b*GDGTs generated from soils are shown in Fig. 5.13 and Table 5.7. MAAT<sub>Weijers2007</sub> and MAAT<sub>De Jonge2014</sub> values show the coolest conditions, while MAAT<sub>Peterse2012</sub> values show warmer conditions (Fig. 5.13). Günther et al. (2014) found that most soil calibrations are invalid in the Tibetan Plateau because the Tibetan Plateau was not included in these soil calibrations, although Günther et al. (2014) found that MAAT<sub>Peterse2012</sub> values were close to observed MAAT for the plateau. The equation proposed by Günther et al. (2014) was used to predict Tibetan MAAT for the studied samples, showing the Pleistocene MAAT were slightly higher than the present temperature. The prediction was similar with MAAT<sub>De Jonge2014</sub> values (Fig. 5.13 and Table 5.7), indicating the temperature is cooling from Pleistocene to present.

Temperature reconstruction functions based on the GDGTs generated from organisms within water are different from those derived from organisms within soils. Thus, the origin of GDGTs can affect the reliability of reconstruction of temperature (De Jonge et al., 2014; Sinninghe Damsté, 2016). Generally, the MAAT is based on lake calibrations (Tierney et al., 2010b; Pearson et al., 2011; Sun et al., 2011; Loomis et al., 2012) were substantially higher MAAT values than observed in present days. The calibration of *b*GDGTs based on lake sediments (i.e. aquatic origin GDGTs) including MAAT<sub>Tierney2010</sub>, MAAT<sub>Tierney2010'</sub>, MAAT<sub>Sun2011</sub>, MAAT<sub>Pearson2011</sub>, MAAT<sub>Loomis2012</sub>, MAAT<sub>Loomis2012</sub> values were clearly higher than soil-based calibrations with large variation. By comparison of India's west Berau delta sediments with global soil I/II/III *b*GDGTs type triangle distribution, Sinninghe Damsté (2016) found that *b*GDGTs of aquatic origin or mixed with aquatic origin were located below the soil samples in the triangular map (Fig. 5.5). As shown in Fig. 5.5, most of the studied samples show a pattern similar to the distribution of *b*GDGTs in modern global soil (De Jonge et al., 2014). The *b*GDGT-II abundances are higher than those of mixed terrestrial/aquatic origin in the Ceará Rise (ODP Site 925) and aquatic origin in the Gulf of Mexico (ODP Site 625) (Crampton-Flood et al., 2021), indicating that the GDGTs are mainly derived from terrestrial soil input. The same conclusion can be drawn from the lower abundances of *b*GDGT-IIIa and higher abundances of *b*GDGT-II (Fig. 5.6; Günther et al., 2014). The #rings<sub>tetra</sub> index was used to evaluate the relative contribution of cyclic *b*GDGTs (Sinninghe Damsté, 2016). In general, #ring<sub>tetra</sub> is increasing with the increase of distance from the coast (Sinninghe Damsté, 2016). If the mean value of #ring<sub>tetra</sub> is greater than 0.7, *b*GDGTs cannot be completely originating from soil (Sinninghe Damsté, 2016). #ring<sub>tetra</sub> values from the studied samples are 0.16-0.85 (avg. 0.45; Table 5.5), indicating that *b*GDGTs in the studied sediments mainly derive from soil. In addition, the high BIT values ranging from 0.72 to 1.00 (avg. 0.89; Table 5.5) indicate the shallow water depth in the study area as well (Sinninghe Damsté, 2016). The phenomenon that most of the *b*GDGTs are catchment soil-derived in some Tibetan lake systems has been observed before (Günther et al., 2014). Combining with the above discussion, *b*GDGT in Tibetan lakes originated mainly from surrounding soils, although the studied samples were sampled from lake sediments. Thus

the MAAT values based on calibration of soil-derived GDGTs are probably more reliable than those based on calibration by lake sediments. According to spore and pollen data as well as oxygen isotopes, there is a cooling trend from 2.8 Ma to present-day (Fig.12) with quite some variability in each time interval. The MAAT fluctuation within the Pleistocene interval is also significant based on our data, e.g. the well calibrated MAAT<sub>Günther 2014</sub> ranging from 0.54 °C to 4.91 °C with an average of 2.23 °C. This is slightly higher than at present-day, but the Pleistocene variability (4.5 °C between coolest and warmest temperature) is greater than the cooling since then.

Fig. 5.13. Comparison of reconstructed temperatures based on soil calibrations in soils and lake sediments as obtained from Eqs. 5.6 to 5.21.

The TEX<sub>86</sub> proxy was used to reconstruct LST (lake surface temperature). A lacustrine (compiled by Castañeda and Schouten, 2011) and a marine calibration (Kim et al., 2008) were used to evaluate the obtained data. Moreover, seasonal influence was estimated by using a study of Powers et al. (2010). The reconstructed LST<sub>Kim2008</sub>, LST<sub>Castañeda2011</sub> and SLST were in agreement with the current measured summer surface water temperature (SLST; Fig. 5.13 and Table 5.7); thus the temperature during the Pleistocene was probably warmer than at present-day. Only the WLST significantly differed from the measured mean water temperature, which is expected, because it reflects the cooler winter temperature (Fig. 5.13 and Table 5.7). Generally, LST has a high correlation with MAAT. However, such a close relationship between both parameters cannot be detected in recent Tibetan lakes due to glacial meltwater input substantially reducing LST, or circulation of warm or cold water volumes within the lakes (Günther et al., 2014). The TEX<sub>86</sub> is affected by a variety of factors (e.g. Schouten et al., 2013); for example TEX<sub>86</sub> is not suitable to calculate temperatures for lacustrine environments, if the lakes were strongly influenced by methanogenesis (Blaga et al., 2009), or if the sediments contain a large number of soil-derived *i*GDGTs (Blaga et al., 2009; Powers et al., 2010). All major groups of archaea except halophilic archaea can generate *i*GDGT-0 (Schouten et al., 2013 and references therein). In most cases, they are regarded as terrestrially sourced biomarkers, even if in situ production of *i*GDGT-0 cannot be

excluded as suggested in previous studies (e.g. Blaga et al., 2009; Bechtel et al., 2010). By contrast, crenarchaeol and *i*GDGTs 1–3 are produced in situ in lake environments (Günther et al., 2014) and are thus used for the TEX<sub>86</sub> calculation. In this study, the TEX<sub>86</sub> reveals LST ranging from 5.7 to 19.6 °C (WLST were 2.4–13.7 °C) (Fig. 5.13 and Table 5.7). Interestingly, MAATs calculated based on lake calibrations (Powers et al., 2010; Tierney et al., 2010a; Castaneda and Schouten, 2011) show strong agreement with the SLT.

#### 5.6.4.2.2 GDGTs as indicator of palaeo-pH and moist/arid conditions

According to Günther et al. (2014) pH and salinity were probably the most influential environmental factors for the relative distribution of *b*GDGTs in the lake sediments, while archaeal lipid distributions were related mainly to temperature (and to a lesser extent pH and conductivity). At present, the mean annual precipitation (MAP) ranges between around 50 mm at the margin to about 25 mm in the central basin with a mean annual potential evaporation of > 3000 mm (Chen and Bowler, 1986; Yang et al., 1995; Jiang and Robbins, 2000); conditions are dry.

Xie et al. (2012) and Yang et al. (2014) found that the high  $R_{i/b}$  values (>0.5) in soil only can be observed in areas where MAP is less than 600 mm and alkaline soils (pH > 7.5) exist. Alkaline soils provide a favorite environment for soil Thaumarchaeota which is a major source organism for *i*GDGTs, thus leading to higher concentrations of *i*GDGTs there (Kim et al., 2012). However, microbes producing *b*GDGTs find best conditions at low pH, e.g. in acidic soils (Weijers et al., 2007b). The high  $R_{i/b}$  values measured on our samples ranging from 0.77–3.40 (1.62 on average) indicate arid and alkaline soils conditions.

There is a close link between the aridity in Central Asia, the major uplift of the plateau, and the development of alkaline sediments in this region that occurred during the Late Miocene (around 8–9 Ma ago) (An et al., 2001; Xie et al., 2012). This corresponds to the first stages of evolution of Asian climates, i.e. the Asian interior drought intensified, and the Indian and East Asian monsoon began, as well as the initial uplift period of the TP. The continued intensification of the east Asian summer and winter monsoons occurred about 3.6–2.6 Ma ago followed by more intense and continuous East Asian winter monsoon conditions and increased variability and possible weakening of the Indian and east Asian summer monsoons since around 2.6 Ma ago (An et al., 2001), resulting in the aridity in Central and East Asia. This evolution is also reflected by the obviously higher Pleistocene  $R_{i/b}$  values derived from this study as compared to those of the Late Miocene on the Tibetan Plateau (Xie et al., 2012). Due to the continuous uplift of the Tibetan Plateau since the Holocene, the Pleistocene  $R_{i/b}$  values are clearly lower than those of the modern northeastern Tibetan Plateau (Sun et al., 2016), indicating a continuous aridification process. The low MBT values for high-altitude areas usually coexist with high  $R_{i/b}$  values, representing a cold and dry environment, as opposed to the high MBT and low  $R_{i/b}$  values, which represent a low-altitude warmer and more humid environment (Fig. 5.11d). The low MBT and high  $R_{i/b}$  values in the studied samples would therefore indicate a cold and dry environment (Fig. 5.11d). Hence, the paleo environment during the Pleistocene period was likely arid and cold. Considering the current

elevation of the Qaidam Basin (2.7-3.5 km) and rapid uplift after the Pleistocene, the high Pleistocene  $R_{i/b}$  values (Fig. 5.11d) probably indicate arid conditions caused by the inland location rather than by very high altitude.

Generally, high pH values indicate an arid environment. Relationships between CBT (cyclisation of branched tetraethers) and pH values were observed for soils samples (Weijers et al., 2007b; Peterse et al., 2010; Xie et al., 2012). For global soils CBT and pH values show a negative relationship (Weijers et al., 2007b; Peterse et al., 2010). Xie et al. (2012) argued that this relationship would be negative in acid environment ( $pH < 7$ ) and that there should be a slightly positive correlation or a flattening off in alkaline environment ( $7 < pH < 9$ ) for all soils collected from different climate zones of China. This positive correlation in soils and surface sediments of Tibetan saline lakes with  $pH > 8$  was also observed by Günther et al. (2014).

In this study, calculated  $pH_{Günther2014}$  values are highest, ranging 8.66 from 9.91 (mean value = 9.13), followed by  $pH_{Tierney2010}$  (8.00-9.37) and  $pH_{Sun2011}$  (7.67-8.37) (Table 5.7). All of these values, however, indicate an arid environment. The pH values based on soil-derived GDGTs (Weijers et al., 2007b) show alkaline environment as well with  $pH_{Weijers2007}$  values ranging from 6.75 to 7.92 (7.5 on average). These new results are consistent with those of previous studies indicating that soils on the Tibetan Plateau tend to be alkaline with pH varying between 6 and 10 (8 on average; Wang et al., 2012; Günther et al., 2014).

## 5.7 Conclusion

This study combines major and trace elements, GDGTs, and stable isotopes of two organic facies from Pleistocene, microbial gas source rocks in the central Qaidam Basin in order to achieve an overview on climatic conditions during that time. The following conclusions concerning origin of organic matter, depositional conditions within the water column, factors controlling OM quantity and quality, and paleo-climatic conditions are drawn:

- 1) The OM of organic facies A is mainly derived from a mixture of C3 higher plants and phytoplankton growing in marginal parts of the lake. This facies is characterized by high TOC contents and abundant terrigenous organic matter.

- 2) Organic facies A were deposited in a shallow freshwater environment under dysoxic to anoxic bottom water conditions, while organic facies B developed in a hypersaline lake environment under oxic bottom water conditions. Based on TOC contents and carbon isotope data, the OM preservation in both organic facies A and B was primarily controlled by the paleo-redox conditions, i.e., the dysoxic to anoxic bottom water conditions for organic facies A and oxic conditions for organic facies B might be the most important factors controlling their high and low TOC content, respectively.

3) Due to the high sedimentation rates, organic carbon accumulation was fast due to rapid burial and thus good preservation of organic matter. According to the negative correlation between TOC content and  $\delta^{13}\text{C}_{\text{org}}$  values, OM preservation was controlled by paleo-redox conditions.

4) There is no significant difference between organic facies A and B with respect to the paleoclimate proxies. Related major and trace elements indicate arid/cold conditions with weak chemical weathering during the Pleistocene. Combined with the published data, the CIA and  $R_{i/b}$  values indicate a rather continuous cooling and aridification process from Miocene to Pleistocene and recent.

5) The *b*GDGTs of the studied samples are mainly derived from terrestrial soil input, and the Pleistocene calculated MAAT based on *b*GDGTs (0.54-4.91 °C, 2.23 °C on average according to the most reasonable calibration) were slightly higher than the present temperature. The reconstructed lake surface temperature ranges from 5.7 to 19.6 °C (WLST were 2.4-13.7 °C). The Pleistocene soils on the Tibetan Plateau were alkaline.

## 6 General discussion and outlook

### 6.1 General discussion

This thesis covers basic non-marine source rock characterization and investigations of hydrocarbon potential for shale gas, shale oil and microbial gas. Concerning the Paleozoic gas shales and Triassic oil shale in the Ordos Basin as well as microbial gas mudstones in the Qaidam Basin, depositional environment, thermal maturity and hydrocarbon potential were analyzed. In addition, factors controlling organic matter (OM) accumulation and records of paleo -environment and -climate evolution in mudstone/shale have been analyzed. The characteristics of the non-marine source rocks covering stages from immature to over mature are investigated within this thesis. Part of the results are in good accordance with those documented in other publications, but some new ideas have been proposed as well. Major conclusions are summarized as follows:

- **Thermal maturity and depositional conditions of Upper Paleozoic shales from the Ordos Basin:**

The Upper Paleozoic gas shales presented in this thesis have over thermal maturities with maturity ranging from 2.35 to 2.97%. The results are similar to the other publications in the similar area showing the maturity of 2.3-3.12% (Ding et al., 2013; Xiong et al., 2017; Yang et al., 2017b). This relatively homogeneous maturity over a wide area corresponds to the rather equal thickness of the over formations along the whole basin. Both in terms of lithology and mineral content, rocks show strong variability, related to variable depositional settings. The values of TOC/TS of the samples studied cover a wide range and indicate the shift from marine to terrigenous environments as well. The observation of abundant vitrinite and inertinite particles, and even coal fragments and roots, indicates the terrestrial origin of most OM. This material certainly represents a former type III kerogen, now strongly converted towards carbon-rich residues, which is consistent with conclusions from previous studies (Yang et al., 2016, 2017b; Xiong et al., 2017). While most samples have a high content of clay minerals, samples B-3 and B-4 show high contents of carbonate. These samples also have low TOC/TS ratios indicating a marine depositional environment. For our sample set, strong marine influence is indicated for Benxi Formation (in agreement with e.g. Ding et al. (2013) and Xiong et al. (2013)), but not for Shanxi Formation where the studied samples do not show any marine influence. Clay minerals are clearly dominated by I/S mixed layer in Shanxi Formation, while Benxi Formation shales are characterized by a mixture of both I/S mixed layer and kaolinite. This non-uniform distribution of clay minerals is consistent with previously published data (Ding et al., 2013; Yang et al., 2016, 2017b; Xiong et al., 2017).

- **Controls on gas storage characteristics of Upper Paleozoic shales from the Ordos Basin:** Both the Benxi and Shanxi shales are characterized by comparatively low porosities, sorption capacities and gas storage capacities compared to producing marine shale gas systems. Excess

sorption capacity and porosity of over-mature Benxi and Shanxi transitional shales are controlled by their high clay mineral content (up to 80%). In contrast to other shales (e.g. Gasparik et al., 2014; Merkel et al., 2015, 2016; Shabani et al., 2018), TOC has a minor effect on gas sorption because of its low content (smaller than 2.3%). The volumetric “free” gas storage prevails in deeper Benxi and Shanxi reservoirs whereas excess sorptive storage generally dominates the total storage capacity of these shale reservoirs at shallow depths. Methane sorption does not have a positive effect on gas production at high pressure. Only when the pore pressure in the matrix is reduced significantly will “excess sorbed” gas contribute to production. This has major implications for deep reservoirs, where pore pressures in the matrix may not be sufficiently reduced before production ceases. Combined with the large amount of clay minerals that make hydraulic fracturing more difficult, these formations are regarded unfavourable for shale gas exploitation.

• **Depositional environment and organic matter composition of shales from the Triassic Chang 7**

**Member in the Ordos Basin:** The Chang 7 member is a typical clay-rich source rock deposited and preserved in a sulphate-poor lacustrine environment in the center of the basin (MW 16 well) and a fluvio-deltaic environment northwestward (MW 1 well) under fresh water and oxic to sub-oxic conditions. The MW 16 well situated close to the center of the former lake shows, however, slightly reducing conditions. The same result can be drawn from the pyrite size and elemental composition data in the similar area, which were previously published (Yuan et al., 2016). OM is composed of a type II-III kerogen. A mixture of lacustrine aquatic algal-bacterial-macrophytic organisms and terrigenous higher plants (mainly composed of conifers) was the main source of OM based on combined organic petrography and biomarker results. Due to the large area of the basin, the composition of OM shows large variation. For example, the OM is composed of a type I-II kerogen in the southern area (Zhang et al., 2020; Fig. 6.1).

Fig. 6.1. Rock-Eval data on the Chang 7 member in the Ordos Basin: comparison of our results and other data from publications (see Chen et al., 2017).

- **Maturity of organic matter-rich shales from the Triassic Chang 7 Member in the Ordos Basin:**

The thermal maturity of the Chang 7 Member source rocks reaches the main phase of oil generation based on vitrinite reflectance, Rock-Eval and most molecular geochemical data. The  $T_{\max}$  values are quite similar to those from previous publications (Chen et al., 2016; Fig. 6.1). This small range of maturity accords with the thickness distribution of the Triassic, Jurassic and Lower Cretaceous rocks in the study area. The study reveals that these source rocks possess good to very good potential for liquid hydrocarbon generation, based on the moderate to very high total OM content, thickness (up to 100 m of source rock within the 60–120 m Chang 7 Member) and Rock-Eval results. The quality of the source rocks is not as good as previously reported (e.g. Xu et al., 2019), which might be caused by the sampling locations further towards the margin of the basin. Best source rock properties are expected in the area of the former central lake.

- **Classification of Pleistocene microbial gas source rocks in the Qaidam Basin:**

These sediments are generally rich in OM, but contain two vastly different organic facies (A and B), which are interlayered with each other. These two organic facies both represent lacustrine systems. Periodically, shallow freshwater fluvio-lacustrine environments similar developed during high water levels at the lake margins with suboxic to anoxic redox conditions in bottom water favoring the development of OM-rich (4.1–25.3 wt.% TOC) and sulphur-rich (1.5–3.7 wt.% TS) sediments. They represent organic facies A, which, however, accounts for only a small proportion of the whole sedimentary sequence. More common is organic facies B, represented by samples with moderate TOC content of 0.5–1.1 wt.% and TS content of 0.1–1.0 wt.%, which were deposited under more oxic bottom waters in more distal parts of the lake.

- **Depositional environment of Pleistocene microbial gas source rocks in the Qaidam Basin:**

The depositional environment of Pleistocene microbial gas source rocks was interpreted based on the TOC/TS ratios, biomarker characters,  $C_{\text{org}}/P$  ratios, trace elements, relative concentrations of TOC, TS and iron, H/C and C/S ratios of kerogen samples. Organic facies A samples were deposited in a shallow freshwater environment without stratification, but organic facies B samples developed in hypersaline depositional environments and partly even in lakes with water column stratification. Moreover, organic facies A samples were deposited under dysoxic to slightly anoxic bottom water conditions, while organic facies B samples were deposited under oxic conditions. However, reducing conditions indicated by biomarker data were probably sometimes present in the sediments caused by the “mat-seal effect”.

- **Composition and maturity of organic matter of microbial gas source rocks in the Qaidam Basin:**

The kerogen type is gas prone mixed type II-III in most samples, which are thermally immature. A large part of it is originated from aquatic higher plants in sediments representing organic facies A, i.e. submerged angiosperms and macrophytes that were growing at the lake margin. In contrast, organic facies B samples mainly developed from algae living in salt water.

Cyanobacteria contributed to the kerogen in both organic facies, while other microbial contribution was more pronounced for organic facies B than organic facies A. Terrestrial higher land plants only provided a minor part of the kerogen.

- **Organic carbon accumulation rate of microbial gas source rocks in the Qaidam Basin:** Both organic facies A ( $75\text{--}450 \text{ g C m}^{-2}\text{a}^{-1}$ ) and organic facies B ( $8\text{--}40 \text{ g C m}^{-2}\text{a}^{-1}$ ) show high calculated organic carbon accumulation rates, which are favorable for rapid burial of kerogen into the methanogenesis zone. They are distinctly higher than e.g. in OM-rich Quaternary marine sediments sites drilled by ODP such as Baffin Bay, Labrador Sea ( $0.1\text{--}3 \text{ g C m}^{-2}\text{a}^{-1}$ ; Stein, 1991). Furthermore, they are greater or close to upwelling areas offshore Peru and Oman ( $0.4\text{--}15.9 \text{ g C m}^{-2}\text{a}^{-1}$  with an average value of  $3.69 \text{ g C m}^{-2}\text{a}^{-1}$ ; Lückge et al., 1996) and open-ocean gyres ( $0.026\text{--}378 \text{ g C m}^{-2}\text{a}^{-1}$  with an average value of  $55.85 \text{ g C m}^{-2}\text{a}^{-1}$ ; Suess, 1980), respectively (Fig. 6.2). This is due to the tectonic setting leading to strong erosion in the hinterland and thus high sediment accumulation rates, combined with lake environments favorable for OM production and preservation. Compared to other lake systems, the values of organic facies B samples are slightly lower and those of facies A are slightly higher than those in Brazilian lakes, such as Feia ( $43 \text{ g C m}^{-2}\text{a}^{-1}$ ; lake altitude is 850 m) and Agua Preta de Baixo ( $22 \text{ g C m}^{-2}\text{a}^{-1}$ ; lake altitude is 240 m), where also large populations of floating macrophytes developed during the Holocene (Turcq et al., 2002). In addition, the wells located above the gas fields show moderate to high SPI (source potential index) values ranging from 2.24 to 25.66  $\text{t HC/m}^2$ , but the T2 Well which is close to Sebei 1 Gas Field shows a lower SPI value ( $1.49 \text{ t HC/m}^2$ ).

Fig. 6.2. Organic carbon accumulation rate in the microbial gas source rocks in the Qaidam Basin: comparison of our results and data on other data from publications.

• **Factors controlling OM organic matter accumulation of microbial gas source rocks in the**

**Qaidam Basin:** The relative importance of palaeoredox conditions and palaeoproductivity as control factors on OM preservation can be evaluated via the relationship between TOC content and  $\delta^{13}\text{C}_{\text{org}}$  value. The OM accumulation in both organic facies A and B was primarily controlled by the palaeoredox conditions, i.e., the dysoxic to slightly anoxic bottom water conditions for organic facies A samples and oxic conditions for organic facies B samples might be the most important factor controlling their high and low TOC content, respectively.

- **Climatic conditions during the Pleistocene in the Central Qaidam Basin:** There is no significant difference between organic facies A and B samples with respect to the paleoclimate proxies. These sediments were deposited under arid/cold conditions with weak chemical weathering during the Pleistocene period. Combined to the mean CIA values of J<sub>1</sub> (88), J<sub>2</sub> (87), J<sub>3</sub> (75), K<sub>1</sub> (71), E<sub>1+2</sub> (68), E<sub>3</sub> (71), N<sub>1</sub> (72), and N<sub>21</sub> (67) mudstones released by Jian et al. (2013), the CIA values indicate a continuous cooling and aridification process (Fig. 6.3). The Pleistocene MAAT (mean annual air temperatures; 0.54-4.91 °C, 2.23 °C on average) were slightly higher than the present temperature. The Pleistocene R<sub>i/b</sub> values are located between the higher modern R<sub>i/b</sub> (Sun et al., 2016) values in northeastern TP and the lower Late Miocene R<sub>i/b</sub> values in the TP (Xie et al., 2012), indicating arid and alkaline soil conditions and a continuous aridification process. Moreover, soils at the Tibetan Plateau tended to become more alkaline with pH varying between 6 and 10.

Fig. 6.3. CIA values for different source rocks in the Qaidam Basin from old (left) to young (right): comparison of our results and data on other data from Jian et al. (2013).

## 6.2 Outlook

During my PhD study, different source rocks in northern China and their hydrocarbon generation potential were investigated. Several topics which remain worth investigating are listed as follows:

- Controls on gas storage characteristics of Upper Paleozoic shales from the Ordos Basin were studied. However, the analysis of the depositional environment using organic geochemical methods of

these non-marine Paleozoic gas shales in the Ordos Basin was limited due to their high thermal maturity. More systematic inorganic geochemical analysis, e.g. using major and trace elements and isotopic studies should be performed as well on these shales. Thermal maturity can be determined accurately by using vitrinite reflectance for such terrestrial shales with very high maturity. In addition, some molecular compounds, e.g. diamondoids, might provide valuable geochemical thermal maturity data and clay mineralogy (e.g. illite crystallinity) would be useful as well.

- The Ordos Basin is the second-largest basin in China. The Triassic Chang 7 Member is the most important source rock for the Mesozoic hydrocarbons in the basin. These source rocks developed a Type II-III kerogen from a typical fresh water lacustrine environment based on the data of molecular geochemistry and Rock-Eval pyrolysis as well as petrographical observations. However, the molecular structures of these kerogens in this area are not studied until now. In the next step, kerogen should be studied comprehensively using FT-IR-spectroscopy, Curie Point-pyrolysis-GC-/MS, X-ray diffraction (XRD), XRF, and ICP-MS to 1) gain new insights into the depositional environment of Chang 7 Member source rocks throughout the mid-western area of the Ordos Basin, and 2) obtain detailed information on structure and chemistry of Triassic lacustrine kerogen in the basin.

# Curriculum Vitae

---

Name: **Jinqi Qiao**  
Tel: **+49 1637500511**  
E-mail address: **jinqi.qiao@emr.rwth-aachen.de**

---

## PERSONAL INFORMATION

Gender: **Male**  
Date of birth: **29/10/1992**  
Birthplace: **Gansu Province (China)**  
Nationality: **Chinese**  
Major: **Geology**  
Ranking: **1/133 (Master period) and 4/27 (Bachelor period)**

---

## EDUCATION

09/2017 – present **Applied Geosciences, RWTH Aachen university, Phd. (with Prof. Dr. Littke Ralf);**  
09/2014 – 06/2017 **Geological Engineering, China University of Petroleum (Beijing), M.Sc. (with Prof. Dr. Luofu Liu);**  
09/2010 – 06/2014 **Geochemistry, Lanzhou University, B.S.**

---
